6 **Abstract.** To describe the sedimentary signal delivered at catchment outlets, many authors now refer to the concept of  
7 connectivity. In this framework, the sedimentary signal is seen as an emergent organization of local **links** and interactions.  
8 The challenge is thus to open the black boxes that remain within a sediment cascade, **which** requires both accurate  
9 geomorphic investigations in the field (reconstruction of sequences of geomorphic evolution, description of sediment  
10 pathways) as well as the development of tools dedicated to sediment cascade **modeling**. More precisely, the development of  
11 tools **devoted** to the study of connectivity in geomorphology is still in progress, although graph theory offers promising  
12 perspectives (Heckmann and Schwanghart, 2013). In this paper, graph theory is applied to abstract the network structure of  
13 sediment cascades, keeping only the nodes (sediment sources, sediment stores, outlet) and links (linkage by a transportation  
14 agent), represented as vertices and edges. From the description of the assemblages of sedimentary flows, we provide three  
15 main indices to explore how small-scale processes may result in significant broad-scale geomorphic patterns. **The main**  
16 **hypothesis is that the network structure dictates how sediment inputs from various sources interact at tributary junctions and**  
17 **finally at the outlet of a cascading system.** First, we use the flow index to assess the potential contribution of each node to the  
18 sediment delivery at the outlet. Second, we measure the influence of each node regarding how it is accessible from both  
19 sediment sources and the outlet (using the Shimbel index). Third, we calculate a connectivity index **revealing** whether the  
20 potential contribution of a node is lower or higher than expected from its location within the network. These indices are **first**  
21 **computed** for a virtual sediment cascade **and then** applied to a catchment located in the southern French **Alps**. **We**  
22 **demonstrate that these indices may lead to simulations of sediment transfer and help in identifying the hotspots of**  
23 **geomorphic change.** In the present case, we try to predict how a sediment cascade may be impacted by an edge disruption or  
24 a reconnection.

## 25 **1 Introduction**

26 The concept of connectivity now provides an overarching framework in geosciences to explore better how catchments  
27 function. Connectivity was first defined in ecology to assess the spatial coherence of a system of landscape elements, a  
28 coherence that is necessary to maintain or restore ecological functions (Bennett, 2004). Following these pioneering  
29 discussions, it has been increasingly used by hydrologists to model hydrological connection patterns (Delahaye et al., 2001;

1 Douvinet et al., 2008). For instance, Ali and Roy (2009) stated that hydrological connectivity can be seen as a function of the  
2 available water volume (calculated from a hydrological balance) and the rate of transfer. More recently, connectivity has  
3 appeared as a fruitful conceptual framework in geomorphology (Brierley et al., 2006; Wainwright et al., 2011; Fryirs, 2013;  
4 Hoffmann, 2015). It helps in studying the spatiotemporal unsteadiness of sediment transport within catchments, and why  
5 sediment cascades can be considered a “jerky conveyor belt” (Ferguson, 1981). Unsteadiness patterns in sediment transfers  
6 are indeed a major field of research for geomorphologists, and refer to the “spatial and temporal paradox” described by  
7 McGuinness et al. (1971): in a catchment, sediment delivery from sources on hillslopes is not correlated with sediment  
8 delivery at the outlet. Consequently, sediment cascades are not necessarily efficient in transferring sediments, highlighting a  
9 “sediment delivery problem” (Walling, 1983). Finally, geomorphic signals, especially sediment delivery, cannot be  
10 interpreted easily (e.g. in terms of climate change, anthropogenic influences, etc.) and may rather reveal a “sedimentological  
11 anarchy” (Walker, 1990; Bravard, 1998; Schumm, 2005). At the catchment scale, geomorphic processes may be alternately  
12 coupled to create a sediment impulse or antagonistic to create a blockage.

13 Recently, many authors have sought a complex-systems approach to conceptualize the continuum of sediment transfer: how  
14 processes, at local scales, may be combined to understand the functioning of the whole sediment cascade (Fryirs et al., 2007;  
15 Borselli et al., 2008; Fryirs, 2013; Bracken et al., 2015). Such a multiscale framework was conceptualized by Heckmann  
16 and Schwanghart (2013), who clearly distinguished the coupling of processes and connectivity. On the one hand,  
17 geomorphic coupling is “the linkage of distinct landforms or landscape units by sediment transport” (Harvey, 2001); it refers  
18 to “elementary interactions at the relatively small scale” (Faulkner, 2008). On the other hand, “the degree of coupling, the  
19 combined effect of lateral (hillslope to channel) and longitudinal (from one river reach to another) linkages between system  
20 components, is termed (sediment) connectivity” (Heckmann and Schwanghart, 2013). Shifting from the local to the  
21 catchment scale remains the main issue in explaining how [erosion and sediment transfer on a small spatial scale interact to](#)  
22 [result in broad-scale geomorphic patterns and processes](#) (Bracken et al., 2015). [It requires the development of numerical](#)  
23 [methods to acquire an exhaustive inventory of all the local linkages within the sediment cascades, to assess their properties,](#)  
24 [and then to predict the result of their combination at catchment scale.](#) One promising field of research has been opened up by  
25 the application of graph theory, [which](#) offers mathematical tools to [analyze](#) statistically the assemblages of all the  
26 components of a [sediment cascade](#). [It is a spatially explicit analysis since nodes and edges are spatial objects and since](#)  
27 [distance plays a role in the modeling](#) (Heckmann and Schwanghart, 2013; Heckmann et al., 2015). [This mathematical](#)  
28 [approach is based on a graph representation of the hydrological network that has been used since decades to describe](#)  
29 [watercourses shape and organization](#) (Strahler, 1957; Shreve, 1974). This methodological framework focuses particularly on  
30 structural connectivity, i.e. the influence of the spatial patterns [formed](#) by the linkages on sediment delivery. One main  
31 objective is to provide a quantitative index that would help in comparing [the skeleton of the sediment cascades](#) in both space  
32 and time. It could also be used to [estimate](#) the contribution of a given part of the catchment to provide sediment at the outlet  
33 and to [predict](#) where [local erosion should be monitored](#) (Cavalli et al., 2013).

1 In this paper, we propose such a connectivity index. Following a brief state-of-the-art regarding connectivity indices, we  
2 explore the main mathematical tools provided by graph theory to measure structural sediment connectivity. We particularly  
3 aim to complement the indices already published in order to develop a framework in which geomorphic simulations of  
4 changes can be carried out. The proposed connectivity index is first described through a fictive and simple sediment cascade.  
5 Then, it is applied to the Celse-Nière study area (French Alps) to explore the spatial patterns of (dis)connectivity within the  
6 catchment based on a scenario analysis. Finally, we discuss the main applications and interpretations of the proposed  
7 connectivity index.

## 8 **2 State-of-the-art**

9 By stating that catchments are inefficient at supplying sediment to the outlet, Walling (1983) pointed out a problem that  
10 arises from (dis)connectivity. He showed that catchments (especially larger ones) tend to be characterized by a low sediment  
11 delivery ratio (SDR).

$$12 \text{SDR} = \frac{V_h}{V_o} \quad (1)$$

13 where  $V_h$  is the volume of sediment eroded from hillslopes and  $V_o$  is the volume of sediment delivered at the outlet of the  
14 catchment. The SDR is a synthetic index that provides a proxy to assess the connectivity of a catchment, and allows  
15 comparisons in both space and time. Recently, it has been demonstrated that SDR (and connectivity) decreases with  
16 increasing landscape morphological complexity (Baartman et al., 2013). One main criticism regarding this index is that  
17 catchments remain a black box: no attention is paid to the geomorphic linkages involved at the local scale, or to the  
18 feedbacks between geomorphic processes (Gumiere et al., 2011; Fryirs, 2013). In this respect, the SDR has been interpreted  
19 as a simple “performance” factor to relate erosion measured at the plot scale to sediment yields observed at the larger scale.  
20 Its usefulness has been critically discussed during recent decades (Hoffmann, 2015).

21 To open such black boxes, the concept of connectivity was subdivided into two distinct parts (With et al., 1997; Tischendorf  
22 and Fahrig, 2000; Turnbull et al., 2008). On the one hand, structural connectivity refers to spatial patterns in the landscape,  
23 such as the spatial distribution of landscape units, which influences sediment transfer patterns and sediment paths. On the  
24 other hand, functional connectivity focuses on how geomorphic processes may activate or block the sediment transfer along  
25 the spatial links within the sediment cascade (Kimberly et al., 1997; With and King, 1997; Belisle, 2005; Uezu et al., 2005).  
26 The latter is now also often called process-based sediment connectivity and was documented in depth in a recent review  
27 (Bracken et al., 2015). Here, we focus on structural connectivity, whose quantification is required to explore and understand  
28 the responses of geomorphic systems (Wainwright et al., 2011).

## 1 **2.1 Assessment of structural sediment connectivity**

2 Borselli et al. (2008) and Cavalli et al. (2013) developed a connectivity index (Eq. 2) that refers to structural connectivity. It  
3 estimates that connectivity at one location within the catchment can be seen as a ratio between an upslope (Eq. 3) and a  
4 downslope component (Eq. 4):

$$5 \quad IC = \log_{10} \left( \frac{D_{up}}{D_{dn}} \right) \quad (2)$$

$$6 \quad D_{up} = \overline{W} \overline{S} \sqrt{A} \quad (3)$$

$$7 \quad D_{dn} = \frac{\sum_i d_i}{W_i S_i} \quad (4)$$

8

9 where W is the average weighting factor of the upslope contributing area, S is the average slope gradient of the upslope  
10 contributing area (m/m) and A is the upslope contributing area (m<sup>2</sup>) and where d<sub>i</sub> is the length of the flow path along the i<sup>th</sup>  
11 cell according to the steepest downslope direction (m), and W<sub>i</sub> and S<sub>i</sub> are the weighting factor and the slope gradient of the i<sup>th</sup>  
12 cell, respectively. In Borselli et al. (2008), the weighting factor W first corresponded to the C-factor of USLE-RUSLE  
13 models (Wischmeier and Smith 1978; Renard et al. 1997) to refer to frictions that hinder sediment transfer. More recently, it  
14 has been demonstrated that topographic surface roughness can provide a good estimation of the weighting factor (Cavalli et  
15 al., 2013; Baartman et al., 2013): a high roughness value is seen as impeding sediment transfer. This index opens up a  
16 fruitful field of research to assess structural connectivity. First, it opens the black boxes within a catchment: the IC can be  
17 calculated for each cell of the catchment, highlighting those cells that may contribute greatly to the sediment flux at the  
18 outlet. Second, this index takes into account all the links between a cell and all other components of the catchment: it nicely  
19 refers to the definition of connectivity. Third, the index can be mapped enabling comparisons between various locations (a  
20 specific tool has been developed in Arc GIS), and the calculation of maps of connectivity evolution over time. Nevertheless,  
21 this index remains empiric, so that comparisons between catchments should be made carefully. More specifically, while such  
22 a method helps in identifying specific configurations that are highly susceptible to sediment delivery, it remains difficult to  
23 provide scenarios of change (e.g. the consequences of land use change, retention basin creation or removal).

## 24 **2.2 Graph theory applications to structural connectivity**

25 Another promising field of research is the application of graph theory, which provides a robust mathematical framework for  
26 describing networks such as sediment cascades (Heckmann and Schwanghart, 2013; Heckmann et al., 2015; Cossart, 2016).  
27 Graph theory is applied to model a network structure as nodes (representing sediment sources, sediment stores and the  
28 outlet) connected by edges (representing linkages by a geomorphological process). Both spatial and topological  
29 configurations of the network and the fluxes associated with the respective edges are responsible for the sediment delivery  
30 at the outlet (Heckmann and Schwanghart, 2013; Heckmann et al., 2015). The goal is thus to obtain a pattern that can be  
31 described by algebraic tools (typology of linkages, identification of local sinks, etc.) to show the overall structure of the

1 sedimentary cascade. Graph theory enables an objective description of the [connections of sedimentary flows, and thus an](#)  
2 [estimation of the potential influence of the network on the amount of sediment load](#). Indices provided by graph theory have  
3 been developed to describe the properties of single landscape units (nodes), sediment pathways (edges) and sediment  
4 cascades (edge sequences = paths). The nodes can be characterized by the number and type of links that may provide or  
5 [transport](#) sediments. Sediment sources are characterized by the [absence](#) of input [links](#); sinks are characterized by no output  
6 link; and other nodes correspond to [connectors whose](#) importance is revealed by their degree (number of input and/or output  
7 links). The links may be characterized by the geomorphic process that carries sediments. Regarding the edge sequences, their  
8 main characteristic is whether or not they contribute to the sediment delivery at the outlet: do they correspond to an  
9 [independent subcascade](#) or not?

10 [Another application](#) is to carry out “flow analyses”: in a directed graph (such as sediment cascades), each edge has a capacity  
11 and each edge receives a flow. A flow must satisfy the restriction that the amount of flow into a node equals the amount of  
12 flow out of it, unless it is a source, which has only an outgoing flow, or a sink, which has only an incoming flow. This  
13 simulation is based on an assumption of flow conservation, [and is a complementary approach to the assessment of sediment](#)  
14 [connectivity](#). In the case of sources with no incoming links, they can be assigned a default common value. Sometimes called  
15 the network effect (Pumain and Saint-Julien, 2010; Czuba and Foufoula-Georgiou, 2015), [this shows how the network](#)  
16 [structure may affect the “potential for creation, persistence, or dispersion of sediment waves”](#) (Gran and Czuba, 2015), and  
17 [finally the total delivery at the outlet](#) (Czuba and Foufoula-Georgiou, 2015; Cossart, 2016).

18 Nevertheless, these indices do not predict the role of sediment connectivity on sediment delivery, especially in the case of  
19 scenarios of changes. New methodological procedures from graph theory need be developed, so we propose here a brief  
20 state-of-the-art of previous studies in which the influence of a spatial network structure on material or immaterial fluxes has  
21 been thoroughly explored using graph theory. Although [such studies have focused on geography](#) (Cole and King, 1968;  
22 [Gleyze, 2008](#)), social networks (Freeman, 1979) or, more recently, ecology (Ludwig et al., 2002; Belisle, 2005), they have  
23 developed some metrics and discussed some concepts particularly relevant in geomorphology: the relationship between  
24 connectivity and the total amount of fluxes passing through the system, and the identification of local hotspots where any  
25 change may have an impact on the whole system (Marra et al., 2014; Czuba and Foufoula-Georgiou, 2014; Czuba and  
26 [Foufoula-Georgiou, 2015; Masselink et al., 2016](#)). In such studies, one key requirement is to provide a hierarchy of the  
27 influence of nodes within the network. Nodes characterized by high connectivity have a considerable influence within a  
28 network as they control the fluxes passing between many others. Such high connectivity nodes are also those where a  
29 disruption would lead to more serious damage of the network’s functioning (Haggett and Chorley, 1969; Newman, 2010)  
30 [and may be considered hotspots. They lie on the largest](#) number of possible paths [within the network. Many indices provided](#)  
31 [by graph theory have been applied to undirected graphs](#) (for a review, see Rodrigue, 2017). Such indices are the result of a  
32 long procedure of research held by geographers to formalize spatial networks and spatial interactions (Pumain and Saint-  
33 [Julien, 2010](#)). From their experience we can avoid difficulties and understand how structural connectivity can be measured in  
34 directed graphs such as sediment cascades.

1 The Betweenness centrality index (B) measures the extent to which a node  $i$  lies on paths between other nodes (Eq. 5):

$$2 \quad B_i = \frac{\sum n_{ijk}}{n_{jk}} \quad (5)$$

3 where  $n_{ijk}$  is the number of paths that exist from a node  $j$  to a node  $k$ , and that pass through  $i$ ; and where  $n_{jk}$  is the total  
4 number of paths within the network, from  $j$  to  $k$ . Such simulation provides a good evaluation of the potential volume that  
5 may pass through the nodes and is helpful in interpreting, the real fluxes observed in each node of the network. One main  
6 criticism is that this index enhances the role of nodes close to the center of gravity of the network and is not really efficient  
7 in ranking the influence of eccentric nodes (Rodrigue, 2017). However, such eccentric nodes are close to the sources of the  
8 network, so that they should be ranked in relation to their importance in sediment transfer. Furthermore, spatial patterns are  
9 taken into account in a simplistic way: the distance (and the friction effect associated to the distance to hinder fluxes) is not  
10 considered. We note that distance can be calculated in different ways: it can represent the length of the path, the time  
11 necessary to travel along the path, the cost necessary to travel, etc. Consequently, various properties of the edges can be used  
12 to approximate the velocity of sediment transfer (Czuba and Foufoula-Georgiu, 2015).

13 The Shimbel index (Shi) takes into account the distance between nodes and considers whether the location of the node  
14 increases or decreases the total length of all possible paths within the network (Eq. 6), (Newman, 2010; Rodrigue, 2017). For  
15 one node  $i$ , it corresponds to the sum of the length of all the shortest paths connecting all other nodes  $j$  in the graph ( $d_{ij}$ ). To  
16 facilitate comparisons in both space and time, this index should be normalized, i.e. divided by the sum of the length of all the  
17 paths in the network, from  $j$  to  $k$  ( $d_{jk}$ ).

$$18 \quad Shi_i = \frac{\sum d_{ij}}{\sum d_{jk}} \quad (6)$$

19 If the Shimbel index is high, then the node contributes to creating long paths within the network (and thus attenuates the  
20 compactness of the network). If the Shimbel index is low, then the node maximizes the compactness of the network. This  
21 index is much more efficient at ranking the influence of eccentric nodes on the network and can be enriched by considering  
22 various types of distance (geodesic, time, etc.). It is considered a very good proxy of accessibility and is thus sometimes  
23 called an “accessibility index”. Nevertheless, we should point out that the lower the Shimbel index, the higher the  
24 accessibility (and thus the connectivity) of the nodes: while counterintuitive, this feature is now well accepted within the  
25 scientific community (Rodrigue, 2017).

26 Both indices enable an in-depth description of the skeleton of a network and highlight the potential impacts of the network  
27 structure on flux patterns. They can thus provide conceptual and mathematical frameworks to explore the structure of  
28 sediment cascades. Nevertheless, they cannot be applied directly to measure sediment connectivity as sediment cascades are  
29 directed graphs, and thus more complicated in terms of mathematical conceptualization.

### 1 **3 Methodology: the Index of Connectivity (IC)**

2 From both recent developments on sediment connectivity metrics and past studies on the applications of graph theory to  
3 spatial networks, we now develop a methodological framework focusing on the analysis of sediment transfer within a  
4 network. At the catchment scale, graph theory helps in identifying specific assemblages and, more particularly, some  
5 subcascades that are not connected to each other. It corresponds to connected components, i.e. a subgraph in which nodes are  
6 all connected to each other (Newman, 2010). Their identification may reveal the spatial fragmentation of the sediment  
7 cascade and thus highlight the extent of the active contributing area in terms of sediment delivery at the outlet.

8 At a more local scale, to provide indices that can measure sediment connectivity within the sediment cascade, we have  
9 developed the calculation of the IC (index of connectivity) which is based on (1) potential sediment fluxes and (2)  
10 accessibility (Fig. 1). The objective is to assess spatially the respective influence of each node on sediment connectivity  
11 inside the catchment area.

12 Two nodes  $i$  and  $j$  are joined or adjacent if there is an edge from  $i$  to  $j$ . Suppose we are given a directed graph with  $n$  nodes,  
13 the graph can be represented by an  $n \times n$  adjacency matrix  $A$ , constructed as follows: if there is an edge from node  $i$  to node  
14  $j$ , then we enter 1 in row  $i$ , column  $j$  of the matrix  $A$ .

#### 15 **3.1 Potential flows in directed graphs**

16 As in undirected graphs, the first issue is to quantify the “network effect” (according to Pumain and Saint-Julien, 2010) to  
17 highlight how the spatial structure of paths influences the amount of sediment transferred to the outlet. In sediment cascades,  
18 only the paths that come from one node  $j$  to the outlet  $o$  have to be considered so that in each node  $i$ , we have to measure the  
19 extent to which  $i$  lies on paths from other nodes  $j$  to  $o$  ( $F_{ijo}$ ). This measurement is divided by the total number of paths that  
20 come from all nodes  $j$  to  $o$  ( $F_{jo}$ ) to reveal the proportion of the total number of paths that lies on  $i$  (Eq. 7).

$$21 \quad Fi = \frac{\sum F_{ijo}}{F_{jo}} \quad (7)$$

22  $F_{ijo}$  and  $F_{jo}$  can be calculated by reconstructing the sediment pathways throughout the cascade. Under the hypothesis of “all  
23 things being equal”, a virtual volume of sediments (1 unit) is set on each node so that a spatially-uniform sediment input is  
24 considered. As suggested by Gran and Czuba (2015) such a theoretical simplification allows the simulation of sediment  
25 wave generation and movement, it exhibits the specific influence of the spatial structure of the network on the sediment  
26 wave pattern. In case of converging flows, the progressive increase of the fluxes is exhibited. In case of diverging flows, the  
27 flow can be subdivided between edges (equally or according to a ratio) so that the complex pattern of sediment wave  
28 generation and movement can also be described. In terms of mathematical procedure, the evacuation of sediment can be  
29 simulated by a multiplication of the adjacency matrix by a matrix representing the sediment sources ( $S_0$ ) (Eq. 8). This is a  
30 one-column matrix, where each row represents a node of the cascade and the value 1 is entered in each row to represent the  
31 virtual volume of sediments at the beginning of the transfer. Each multiplication corresponds to an iteration, in which each

1 sediment unit is transferred along one edge, according to the links described by the adjacency matrix (Eq. 8 and Fig. 1). The  
2 result provides a matrix  $S_1$ , highlighting where the sediments are after one single iteration.

$$3 \quad S_n = S_{n-1} \times A \quad (8)$$

4 The operation is repeated until all the virtual sediments are evacuated, and the results can be represented within a synthetic  
5 matrix ( $S_n$ ), concatenating  $S_0, S_1, \dots, S_n$  matrices, obtained during the calculation (Fig. 1).

### 6 **3.2 Accessibility from sources to sinks**

7 Within a sediment cascade, the influence of geomorphic units (sources, stores, and sinks) on sediment delivery can be  
8 assessed by considering their location inside the cascades. The central hypothesis is that a node whose distance between the  
9 sediment sources and the outlet is minimal has a greater influence on the overall sediment cascade. In other words, if such  
10 strategic nodes are disconnected from the outlet (i.e. if an edge connecting the strategic nodes is disrupted), the spatial  
11 pattern of the transport capacity changes. Not only would the total amount of sediment fluxes change, the “mutual  
12 interferences” that occur at such geomorphic hotspots would also be modified (Benda, 2004a; 2004b). Characterizing the  
13 nodes by their location within the network refers to the concept of accessibility and is thus very similar to the calculation of  
14 the Shimbel index in the case of undirected graphs. In directed graphs, the calculation of the accessibility ( $Shi$ ) of each node  
15  $i$  can be made from a distance matrix  $D$  (Eq. 10 and Fig. 1):

$$16 \quad \overline{Shi}_i = \frac{D_{\cdot i} + D_i}{D_{\cdot\cdot}} \quad (10)$$

17 where  $D_{\cdot i}$  is the total of the distances between  $i$  and the nodes (sources and stores) that feed  $i$ ,  $D_i$  is the distance between  $i$  and  
18 the nodes located downstream, and  $D_{\cdot\cdot}$  is the total of the distances of all the paths within the network. The main interest of  
19 this index is that it enhances the sources (where  $D_{\cdot i}$  equals 0) and, more particularly, the sources that minimize the distance  
20 to the outlet.

### 21 **3.3 Combination of indices**

22 The indices  $F$  and  $Shi$  provide a quantitative and complementary description of the sediment cascade skeleton: the first  
23 reveals the potential proportion of sediment discharge passing through each node; the second measures the proportion of  
24 potential paths (from all points within the catchment and the outlet) that lie across each node. Classically, the potential  
25 sediment discharge at a node increases in relation to the number of paths that come from sources (i.e. the active contributing  
26 area is larger). Nevertheless, due to the geometry of paths, confluences and, more generally, the network structure, there can  
27 be some interference in terms of sediment movement through the system: the sediment discharge at a node can be higher or  
28 lower than expected from the single number of paths supplying sediments. To estimate this possible under- or  
29 overrepresentation of potential sediment volume at each node, a ratio between  $F$  and  $Shi$  can be calculated (Eq. 11 and  
30 Fig. 1):

$$31 \quad IC_i = \frac{F_i}{A_i} \quad (11)$$

1 The expected results can be **considered** a normalization of the potential sediment fluxes  $F_i$ .

2

### 3 **3.4 Implementation**

4 From a geomorphological map, a graph can be digitalized in GIS software (QGIS), which consists of depicting a regular  
5 network of nodes. Each node can be characterized by the geomorphic unit to which it belongs, and the linkages between the  
6 nodes can be digitized from geomorphological expertise. The links correspond to directed fluxes, driven by gravity, and we  
7 only consider converging flow. To simplify the network structure, each node cannot have two output links. The “Network”  
8 QGIS tools can be used to generate the adjacency matrix (as an edge list matrix) and exported to R software. In the latter, the  
9 matrix was converted into an origin-to-destination matrix, and the distance matrix was automatically created (a topological  
10 distance was considered) using the igraph package. All calculations on matrices were conducted in R, and the results  
11 exported to QGIS to be mapped.

## 12 **4 Results and interpretation**

### 13 **4.1 Implementation on a virtual catchment**

14 To address the role of network structure in sediment fluxes, a **reduced-complexity network is first used**. The indices are  
15 calculated on a small virtual catchment of 7 nodes and 6 links (Fig. 2a), from the **following** parameters: the adjacency matrix  
16 and the distance matrix (Table 1 and 2). The first model run is parameterized in a simplistic way **so that** all sources are  
17 assumed to be of equal importance, using spatially-uniform sediment inputs (volume availability equals 1 at each node at  
18 time 0) and a topological distance (each edge corresponds to a distance of 1 unit).

#### 19 **4.1.1. Potential fluxes**

20 First, a map of the potential **fluxes** within the sediment cascade can be drawn (Fig. 2b and 2c, Table 3). Such a result can be  
21 useful for defining a local monitoring strategy (e.g. survey locations) for sediment transfer and then interpolating local  
22 measurements at the catchment scale. Moreover, the  $F_i$  index may provide a hierarchy between the nodes by assessing the  
23 increase in sediment upstream and downstream of the node. For instance, in our virtual study case, the amount of sediment  
24 classically increases downstream, as there is no interruption of the cascade **and we only consider converging flow**.  
25 Nevertheless, the main increase occurs at node D, pointing out that this node is a junction where there is interplay between  
26 various tributary systems. D may correspond to a zone of sediment persistence within the catchment, so that any disruption  
27 of this node (blockage due to an overflow of sediments, anthropogenic action, etc.) would significantly modify the  
28 development of the sediment pulse. However, one main criticism is that the  $F_i$  index **pays** little attention to the sediment  
29 sources (here A, B and G), (Fig. 2c). As it corresponds to the initiation zones of the sediment cascade, the events that happen  
30 there may influence long pathways to the outlet. As mentioned for the Betweenness index (B), it is necessary to discriminate  
31 better the potential influence of sources and stores located next to sources.

#### 32 **4.1.2. Accessibility**

1 The accessibility map can then be computed based on the distance matrix (Fig. 3 and Table 2). Here, G is characterized by  
2 better accessibility, greater than A, greater than B: indeed the short distance between G and the outlet suggests it would have  
3 a higher influence on sediment delivery. From a geomorphic point of view, it reveals that the time of sediment transfer is  
4 short and the possibility of intermediate storage is low. Figure 3 thus illustrates such a hierarchy of the influence of sediment  
5 sources on sediment delivery at the outlet. In terms of management, it highlights the sources that can be activated to cope  
6 with sediment exhaustion at the outlet or, conversely, sources where protection strategies should be applied in the case of  
7 sediment overflow. Because of this issue, this index is not a good proxy of connectivity as it underestimates the role of the  
8 outlet and all nodes close to the outlet, and does not pay attention to the confluences between various pathways inside the  
9 sediment cascade. At the catchment scale, the roles of D and E are not shown although they are important connectors  
10 between pathways developed from sources A and B. The indices of both nodes have to be carefully compared to note that D  
11 is closer to different sources and the outlet than E.

12

### 13 4.1.3. Index of connectivity (IC)

14 The IC provides synthetic metrics, suggesting that E and D are the most important geomorphic hotspots (Fig. 4), with very  
15 similar values (0.8 and 0.71, respectively). E and D are at confluences and thus lie on various sediment paths from distinct  
16 sources. Their potential influence on the whole sediment cascade is high, so that any disruption of these nodes would  
17 considerably alter the elementary interactions between many nodes and sediment paths. Consequently, D and E may  
18 significantly modify the ability of the cascade to provide sediments and should be further studied in depth to document the  
19 functional connectivity or to assess erosional rates (local monitoring, field observations). The outlet F has a quite high index  
20 (0.66) but lower than E and D. This value highlights that the connectivity of a node is not proportional to the total volume of  
21 sediment that passes through it. In the case of F, the IC is partly influenced by the high potential sediment volume that passes  
22 through it but we point out that any disruption at this node would be ambiguous. For example, it would interrupt the  
23 sediment delivery but the organization of the three tributary subcascades from sources A, B and G would not be modified.  
24 Furthermore, the patterns of mutual interferences at the confluences (E and D) would also remain unmodified, so that  
25 sediment pulse generation and movement would not be modified. Consequently, the spatial structure of the cascade network  
26 would be roughly unchanged under the hypothesis of F disruption. Regarding the sources (A, B and D): a hierarchy is  
27 evidenced. The source G has a greater influence on the sedimentary signal at the outlet due to its proximity (IC = 0.53),  
28 which is greater than A and B (IC equals 0.27 and 0.12, respectively).

29

### 30 4.1.4. Sensitivity of IC to sediment availability

31 To investigate how sensitive the indices are to parameterization, we modify the initial conditions of our virtual sediment  
32 cascade. Regarding sediment availability, we consider G exhausted (volume equals 0) and B overflowing (volume equals 2).  
33 All other nodes remain unchanged. Regarding the distance between E and F, it is now twice the initial value ( $D_{EF}$  equals 2),  
34 (Fig. 5a and Table 4).

1 To interpret the result we first differentiate nodes whose connectivity increases and nodes whose connectivity decreases. As  
2 expected, the potential flow  $F_i$  is mainly modified at B whose influence increases ( $F_B$  shifts from 0.05 to 0.07), and at G  
3 whose influence becomes null (Fig. 5b and Table 4). At other nodes, an increase is observed at D ( $F_D$  shifts from 0.18 to  
4 0.21) while  $F_E$  and  $F_F$  remain roughly unchanged (shifting from 0.80 to 0.85 and 0.66 to 0.56, respectively). While the node  
5 D was already strategic in the first simulation, the increase in sediment availability at B reinforces its influence on the whole  
6 sediment cascade. Downstream, the potential flow at E and F is not reinforced by the amount of sediment delivered at B  
7 because of the exhaustion of G.

8 Considering the accessibility (Fig. 5c), the higher eccentricity of F has an impact on  $A_F$  but, more generally, alters the  
9 accessibility of all nodes. The accessibility coefficient decreases significantly at B: the subcascade organized from B is the  
10 longest and all the sediment paths that may exist along this subcascade are impacted by the greater distance between E and F.  
11 As a consequence, the outlet is here significantly less accessible from the source B than from the sources A and G (the latter  
12 remaining the closer). It can be noticed that the accessibility of D is not impacted by the higher eccentricity of F.  $A_D$  remains  
13 roughly stable, and even suggests a slight improvement in accessibility. All nodes that are characterized by great centrality,  
14 and that are closer to both the sources and the outlet, are not affected by an increasing eccentricity at the margins of the  
15 cascade (if the distance from sources, or to the outlet, increases).

16 Finally, regarding the connectivity index (Fig. 5d), the new parameterization modifies the hierarchy of nodes. First, the  
17 influence of the confluence nodes increases and, concomitantly, the influence of F decreases. As F is characterized by  
18 eccentricity, its influence on the overall system decreases. A disruption would modify the sediment cascade structure less  
19 (interplay at tributary junctions, organization of tributary subcascades) than in the previous run model. D here appears as a  
20 node of high connectivity as it is close to two main sources and to the outlet. The node E is also of prime importance in terms  
21 of connectivity, but its IC value is rather lower than expected from its strategic location. In fact, it is connected to an  
22 exhausted source (G). Looking at the sources, a hierarchy is clearly observed: the influence of B increases due to its main  
23 contribution to the sediment flow, while the influence of G becomes null as it is exhausted.

24 The IC thus reveals the degree of coupling to both the sources and the outlet for each unit of a sediment cascade. More  
25 precisely, it reflects the structural connectivity as it enhances the role of spatial patterns (distance, confluences, etc.) of the  
26 network. To make the interpretation easier, a high connectivity node may modify the overall spatial network structure in the  
27 case of disruption (e.g. modifications of flux interplay at junctions, creation of independent sediment subcascades  
28 unconnected to the outlet, etc.). Moreover, the parameterization could be gradually enriched with geomorphic expertise to  
29 pay more attention to sediment availability or to the ability of geomorphic processes to transfer sediment along the paths (i.e.  
30 the edges).

#### 31 4.2 Application to a real sediment cascade

32 The IC is now applied to a real sediment cascade, whose functioning has already been conceptualized and quantified  
33 (Cossart and Fort, 2008; Cossart, 2016).

### 1 4.2.1 The Celse-Nière catchment

2 The Celse-Nière catchment is located in the French Southern Alps, on the eastern flank of the Massif des Écrins (Fig. 6). The  
3 current glaciation of this catchment is limited (about 6 km<sup>2</sup>), in spite of high altitudes (summit approaching 4000 meters at  
4 Ailefroide), because this area is partly sheltered from oceanic influences due to its eastward location. For instance,  
5 precipitation is about 995 mm.yr<sup>-1</sup> at Pelvoux (1280 meters), which is significantly lower than on the western flank of the  
6 Massif des Écrins (1195 mm.yr<sup>-1</sup> at Valjouffrey, 1160 meters). The equilibrium line altitude ranges from 3000 to 3200 m  
7 (Cossart, 2005), which is 200 meters higher than in the western part of the massif.

8 We focus here on the headwater (about 10 km<sup>2</sup>, from 2500 m.asl to 3850 m.asl), which is still occupied by glaciers. Some  
9 small tributaries converge into the upper part of the catchment (Ailefroide, Coup de Sabre) as their mouth is blocked by the  
10 Sélé glacier valley tongue. Such small catchments are occupied by cirque glaciers, which lie just below granitic and gneissic  
11 free-faces and provide both sediments and meltwater to the valley floor. Special attention has already been given to the  
12 linkages between the glacial margins and the glacio-fluvial systems (Cossart, 2004, 2016). The presence of morainic ridges  
13 still interrupts the sedimentary cascade system, thus forcing local aggradation and change in the glacio-fluvial pattern (Fig.  
14 6). Such a complex assemblage makes this area particularly suitable for assessing connectivity and simulating the impacts of  
15 new blockages or, conversely, some reconnections.

### 16 4.2.2 The structure of the network

17 As in the virtual case study, a reduced-complexity network model is considered to address the role of the network's spatial  
18 structure (Fig. 7). The initial conditions of run 1 of the model are (1) a spatially-uniform sediment input (volume availability  
19 equals 1 at each node at time 0) and (2) topological distance is considered (each edge corresponds to a distance of 1 unit).

20 First, it can be noticed that only 56% of all the paths are connected to the outlet while the others are connected to permanent  
21 sinks. Twenty-five connected components are identified, highlighting a high fragmentation of the system: only 6 of these  
22 encompass more than 10 nodes (including the main connected component connected to the outlet) and 11 encompass fewer  
23 than 5 nodes. By applying the typology established by Fryirs et al. (2007), disconnections are due to barriers, buffers and  
24 blankets (Fig. 7a). Barriers are here mostly due to moraines: lateral moraines may affect the longitudinal coupling of  
25 processes, especially the coupling between glacio-fluvial streams from the cirque glaciers and the mainstem. In that case, the  
26 node that corresponds to the upper part of the moraine is a sink, the node corresponding to the downslope part of the moraine  
27 is a source, but there is no link between these both nodes.

28 Buffers correspond to moraines, where they decouple scree deposits from the mainstem (scree deposition is forced by the  
29 morainic ridge), but also roches-moutonnées and glacio-fluvial terraces. Blankets correspond to scree deposits made of large  
30 grain-size boulders that cannot be removed by fluvial processes. Second, the IC highlights the influence of the trunk valley  
31 located between the margin of the Glacier-du-Sélé and the confluence with the Coup-de-Sabre proglacial river where high-  
32 connectivity nodes are observed (Fig. 6A). This means that potential sediment fluxes are higher than expected from the

1 active contributing areas upstream, so that the network may develop here some zones of potential sediment persistence  
2 within the catchment. Furthermore, such nodes correspond to tributary junctions between the main subcatchments of the  
3 system. The mutual interference may here have an influence on the generation of sediment pulse, and thus on its evolution  
4 (transfer to the outlet), as well as on the tributary subcatchments located upstream. Sediment persistence, an aggradation pattern  
5 in these zones, may generate a retrogressive aggradation that may modify the functioning of subcatchments (e.g. decrease in  
6 sediment transfer along subcatchments in the case of impoundment). For these reasons, such nodes can be considered hotspots  
7 of geomorphic change, which can propagate a perturbation along the whole cascade due to a geomorphic change, and thus  
8 modify the overall functioning of the system. A significant input of sediments (due, for instance, to a hydro-meteorological  
9 event) in these areas would increase the sediment delivery at the outlet and may also alter the ability of tributaries to deliver  
10 sediments. The IC also exhibits a hierarchy between the sources. As they are closer to the outlet, all the sources located in  
11 the Coup-de-Sabre subcatchment have a greater influence on sediment delivery than the sources located in the Ailefroide,  
12 Sélé or Boeufs-Rouges areas.

13 Thus, the map of the IC helps to conceptualize the continuum of sediment transfer and to predict the downstream transfer  
14 and delivery of sediment fluxes measured at one point (not necessarily at the outlet). Node connectivity may need to be  
15 examined to establish sampling strategies for small-scale measurements of erosion in the field. Furthermore, this first  
16 examination highlights that the potential impacts of external drivers (anthropogenic impact, hydro-meteorological event and,  
17 more generally, climate change) are space-dependent: the impacts may be greater and efficiently propagated if they affect  
18 high-connectivity areas.

#### 19 **4.2.3 What if...?**

20 The connectivity hierarchy between nodes can be interpreted as the potential influence of the node on sediment delivery and  
21 the overall functioning of the cascade. The IC and, more generally, tools provided by graph theory enable the simulation of  
22 scenarios to predict which events would have more impact on the cascade. Two other model scenarios were applied here in  
23 R to simulate the consequences of a local disconnection and a local reconnection. Run 2 corresponds to an algorithm that  
24 tests which edge removal would have the greatest impact on sediment connectivity (i.e. the largest decrease in connectivity  
25 at the node characterized by the highest connectivity), (Fig. 7b). This simulation could reflect the possible impact of an  
26 anthropogenic feature (e.g. a dam) or a hillslope process (e.g. a dam created by a landslide mass or a debris flow). Run 3  
27 (Fig. 7c) corresponds to an algorithm that tests which creation of a new edge would lead to the greatest improvement in  
28 connectivity (i.e. where can we create the highest increase in the IC value at a node?). This simulation could reflect the  
29 disruption of a barrier or the removal of a blanket, for instance following a high magnitude geomorphic event.

30 Run 2 highlights that the greatest impact would occur if the edge located at the toe of the Glacier du Sélé was disrupted. It  
31 would lead to the disconnection from the outlet of the main subcatchment (fed by Sélé sediment sources) so that only 40% of  
32 the nodes would remain connected to the outlet (against 56% in the initial stage). Nevertheless, the modification of the whole  
33 system is not just a question of sediment delivery at the outlet. First, we point that that it may provoke an attenuation of the

1 peak of the sediment wave if we compare the simulated sedimentographs between runs 1 and 2 (Fig. 8). Second, the  
2 disruption creates a subdivision of the sediment cascade connected to the outlet into two main connected components of  
3 quite similar size. The connected component that becomes disconnected from the outlet after run 1 (Boeuifs-Rouges area)  
4 encompasses 72 nodes, and the other (still connected to the outlet) 142 nodes. Any other edge removal would lead to a new  
5 connected component of a smaller size (<72 nodes). The disruption would be more significant than that of an edge located at  
6 the confluence with the Coup-de-Sabre proglacial river. In this latter case, many nodes would be disconnected from the  
7 outlet, but the three subcascades of Ailefroide, Sélé and Boeuifs-Rouges would be less impacted and would still be self-  
8 organized within a large connected component. As a result, the structure of the sediment cascade would be less fragmented.  
9 Finally, the IC shows where a local disruption may split two connected components of quite similar size, which may have a  
10 strong impact in terms of geomorphic functioning. As many geomorphic processes are scale-dependent, some variables  
11 influencing sediment transfer that are interdependent at one scale may well be independent at another (Schumm, 2005). A  
12 corollary is that the split of a cascade into two connected components (whose sizes are approximately half that of the initial  
13 cascade) may modify the scale at which geomorphic processes or controls act and markedly change the functioning of the  
14 system.

15 For run 3, a new edge is added to improve the overall sediment connectivity (Fig. 6C). In this case, a link between the  
16 Guyard subcatchment and the trunk valley would create the highest IC value at the confluence. Such an increase is due to the  
17 large number of nodes (64%) that would become connected to the outlet. Furthermore, these nodes (especially the sources)  
18 are relatively close to the outlet, so that the sediment wave exhibits an increase at the beginning of the pulsation (Fig. 8). A  
19 reconnection of the subcascade in the Ailefroide area would have a lesser impact because of its eccentricity. It can be noticed  
20 that the reconnection of the Guyard subcascade would decrease the influence of the Coup-de-Sabre subcascade on the overall  
21 network: in this scenario of reconnection, all the sources of this area are affected by a decrease in IC. According to this new  
22 cascade structure, the hierarchy of sources would be modified: the sources of the Guyard area would have a greater influence  
23 than the Coup-de-Sabre sources, which would have a greater influence than the Ailefroide, Sélé and Boeuifs-Rouges sources.  
24 The IC provides an exploration of the cascade structure and may explain to what extent a small-scale modification  
25 (disruption of a node, creation of a linkage) may result in significant changes in broad-scale geomorphic patterns and  
26 processes. In the present examples, it can also predict the potential impacts on the sediment wave pattern (Fig. 8). More  
27 generally, the IC enables comparisons between different states of connectivity within the same catchment.

## 28 **5 Discussion**

29 Several papers have already addressed the question of the assessment of connectivity (Borselli et al., 2008; Cavalli, 2013;  
30 Czuba and Foufoula-Georgiu, 2015; Gran and Czuba, 2015; Hoffmann, 2015) so we discuss here the potential improvements  
31 offered by graph theory. Following Heckmann and Schwanghart (2013), a graph provides both a geometric and an algebraic  
32 description of the sediment cascade network. By identifying the connected components within the system, the examination

1 of the geometry of the graph first helps to assess the SDR at the catchment scale and to identify the recurrent types of  
2 process coupling. In detail, it aims to determine the interaction of processes that are (in)efficient within the cascade at  
3 supplying sediments to the outlet. From the case studies developed here, we also highlight how an algebraic framework may  
4 help in exploring how the cascading system functions. Reduced-complexity network models associated with simple  
5 hypotheses (spatially-uniform sediment inputs, simple assessment of the distance between nodes based on a topological  
6 distance) highlight the zones of greater sediment persistence, where sediment may accumulate in the network. Consequently,  
7 the role of the network's spatial structure in the generation of a sediment wave can be simulated and the associated  
8 sedimentograph can help in deciphering what is really due to external boundary conditions in sediment delivery variability at  
9 the outlet (Fryirs, 2017). Another result is the rank assessment of the geomorphic importance of the nodes, considering their  
10 location within the catchment. Following previous authors (Cavalli et al., 2013; Czuba and Fofoula-Georgiou, 2015; Gran  
11 and Czuba, 2015), the IC identifies some specific zones that correspond to hotspots of geomorphic change due to their  
12 strategic location closer to the sources and the outlet. One main improvement in the graph theory framework is that the  
13 algebraic description helps in developing simulation scenarios, while the associated algorithms show the properties of such  
14 geomorphic hotspots. They not only influence the total amount of sediment that is delivered at the outlet but they also reveal  
15 where disconnections or reconnections may have a strong impact on the organization of the sediment cascade. A  
16 disconnection occurring at a hotspot may split the cascade into connected components of quite similar size, modifying the  
17 sedimentograph pattern, and may break the organization of path sequences.

18 Such a focus on the spatial dependence of geomorphic processes should be complemented, and the graph can be gradually  
19 enriched to take into account more complexity. A geomorphic hierarchy of sources (in terms of sediment supply) can be  
20 parameterized: for instance, if a source overflows or, conversely, is exhausted. The matrix representing the sediment sources  
21 can then be adjusted. Second, distance is an important parameter that can modify the results of  $A_i$ , and thus  $IC_i$ . Distance  
22 involves friction, which hampers the sediment transfer: the greater the distance, the higher the potential friction opposing  
23 sediment delivery (i.e. the transfer time increases). Many other kinds of distance can be taken into account, such as the  
24 Euclidian distance, but in geomorphology other types of distance may be more relevant. For example, a distance expressed  
25 as a time, to reveal the duration of sedimentary transfer from one unit to another, can be particularly appropriate, although  
26 difficult to assess. A cost distance can also be relevant. By revealing how hampered (or efficient) the sediment transfer is  
27 along the edge, a manning coefficient, or more generally a roughness index (Baartman et al., 2013), can be a good proxy of  
28 the friction that hampers the sediment transfer. Such parameters can be calculated from high-resolution DEM, combined  
29 with the edge characteristics through GIS procedures, and finally integrated within the matrices necessary for the  
30 calculations. In this way, graph theory provides a methodological framework that can be extensively enriched by various  
31 parameters to reveal the transport capacity, and consequently the potential interplay between network geometry and spatial  
32 patterns of transport. One perspective of research is to complement this approach by a more dynamic modelling of the  
33 sediment cascade network structure. It is well-known that the assemblages of links and nodes may evolve in accordance with  
34 various external forces (e.g., climate, human practices, tectonics). For instance, agent-based models can be suitable to predict

1 the possible evolution of the structure, by considering negative and/or positive feedbacks along the edges (Reulier et al.,  
2 2016).

### 3 **6 Conclusion**

4 This paper seeks to develop an original methodology dedicated to the study of [sedimentary cascades under the hypothesis](#)  
5 [that the influence of connectors and paths on sediment](#) delivery is space-dependent. The methods rely on graph theory to  
6 assess structural connectivity: the sediment cascade is described as a network and consequently as a graph. Inspired by  
7 indices developed in other sciences (transportation science, sociology, ecology), a potential flow and an accessibility of  
8 geomorphic units (i.e. accessibility to sediment sources and to the outlet) can be measured throughout the sediment cascade.  
9 Both indices are combined to estimate a connectivity index, which reveals how influential a node is within a sediment  
10 cascade. Specific applications were implemented in GIS software (QGIS) as well as in software dedicated to data analysis  
11 and [matrix](#) calculations (R).

12 The application on a simple virtual catchment and then on a real catchment [shows how the network spatial structure](#) may  
13 lead (or not) to sediment mobilization and exportation, from the upper slopes to the outlet of watersheds. The behavior of  
14 sediment cascades appears space-dependent: the geometry of paths and the location of nodes have a direct influence on  
15 structural connectivity and thus on the ability of the sediment cascade to deliver sediments. As a consequence, some hotspots  
16 of geomorphic change can be identified within the catchment. The impact of an external force on the sediment cascade  
17 depends on the location of its action: the higher the connectivity of the node, the higher the impact on the cascade. Moreover,  
18 some simulations can be [conducted](#) to predict how local perturbations may have an impact on the overall cascade.

19 This issue ([characterizing sediment connectivity at the catchment scale](#)) is one of the main challenges in geomorphology and  
20 may help in understanding how a sediment wave develops and moves downstream. In detail, it may be possible to decipher  
21 better if sediment pulses reveal the spatial network structure or external boundary conditions (e.g. climate change,  
22 anthropogenic pressure, tectonics). [Such results are of importance for management issues](#), for instance in the discussion of  
23 the location of a retention basin for sediments in a context of severe erosion, or where sediment continuity should be restored  
24 to cope with sediment exhaustion in some rivers.
