SHORT COMMUNICATION:
Massive Erosion in Monsoonal Central India
Linked to Late Holocene Landcover Degradation

Abstract

Soil erosion plays a crucial role in transferring sediment and carbon from land to sea, yet little is known about the rhythm and rates of soil erosion prior to the most recent few centuries. Here we reconstruct a Holocene erosional history from central India, as integrated by the Godavari River in a sediment core from the Bay of Bengal. We quantify terrigenous fluxes, fingerprint sources for the lithogenic fraction and assess the age of the exported terrigenous carbon. Taken together, our data show that the monsoon decline in the late Holocene, later exacerbated by the Neolithic adoption and Iron Age extensification of agriculture on the Deccan Plateau, significantly increased soil erosion and the age of exported organic carbon. Despite a constantly elevated sea level since the middle Holocene, this erosion acceleration led to rapid continental margin growth. We conclude that in monsoon conditions, aridity boosts rather than supresses sediment and carbon export acting as a veritable monsoon erosional pump modulated by landcover conditions.
1. Soil Erosion in the Holocene

On decadal to millennial timescales, climate is the principal natural control on soil erosion within a watershed via changes in temperature and precipitation as well as their impact on vegetation type and cover (Allen and Breshears, 1998; Reichstein et al., 2013). Global sediment budgets for the Holocene indicate that humans surpassed these natural controls and became the main driver of soil erosion by at least 2000 years ago (Montgomery, 2007; Wilkinson and McElroy, 2007; Dotterweich, 2013). Transfer of sediment, carbon and solutes from land to ocean is of crucial importance for understanding continental margin architectures as well as carbon and other elemental cycles. For example, soils contain about two times more carbon than the atmosphere and, as a result, small changes in the residence time of organic carbon in soils can significantly affect the atmospheric inventory of carbon dioxide (Lal, 2004). Besides heterotrophic microbial respiration, erosion is the principal process that releases carbon from soils. Eroded carbon can subsequently be degraded/reburied along the aquatic continuum to the ocean (Stallard, 1998; Aufdenkampe et al., 2011; van Oost et al., 2012).

In the absence of historical documentation of human impacts, the complexity of soil erosion hampers the reconstruction of carbon transfer processes prior to the last few centuries (e.g., Hoffmann et al. 2013; Dotterweich, 2013; Vanwalleghem et al., 2017). Consequently, global carbon budgets implicitly assume steady state conditions for lateral transport and carbon degradation along the aquatic continuum in pre-industrial times (Battin et al., 2009; Regnier et al., 2013; Chappell et al., 2015). In contrast, abundant archaeological and geological evidence (e.g., van Andel et al., 1990; Bork and Lang, 2003; Bayon et al., 2012; Dotterweich, 2013) as well as modeling (Kaplan et al., 2010; Wang et al., 2017) suggests widespread impacts of early human land use on continental landscapes, soil erosion and associated carbon transfer processes.

Here we present a soil erosion history from the Indian peninsula recorded in a sediment core retrieved near the mouth of Godavari River (Fig. 1) in the Bay of Bengal (NGHP-01-16A at 16°35.6’N, 82°41.0’E; 1,268 m water depth; Collett et al., 2015). The age model for the core based on 11 radiocarbon dates on mixed planktonic foraminifera was previously published by Ponton et al. (2012). The Godavari basin was not affected by tectonics at the Holocene time scale, or glacial/snow meltwater and strong orographic precipitation, which augment and complicate the water and sediment discharge of the larger Himalayan rivers like the Ganges or Brahmaputra. Instead, it integrates rainfall from the core monsoon zone (CMZ), the region of central India that is representative for both the mean monsoon regime and its fluctuations over the peninsula (see Ponton et al., 2012 and references therein). Consequently, over 90% of Godavari’s water discharge into the Bay of Bengal derives from summer monsoon precipitation (Rao et al., 2005), making its sedimentary deposits a prime target for continental climate reconstructions and a
repository for sedimentary proxies of erosion prior and after the Neolithic adoption of agriculture in central India.

2. The Godavari Sediment System

Originating at an elevation of 920 m in the Sahyadri coastal range (aka Western Ghats) near the Arabian Sea coast, the Godavari crosses the entire Indian peninsula toward the Bay of Bengal (Fig. 1a). Because the coastal range limits penetration of the Arabian Sea moisture delivered by the monsoon (Gunnell et al. 2007), precipitation in the Godavari basin primarily originates from the Bay of Bengal. As a result, the climate is most humid at the coast (i.e., Eastern Ghats range) and becomes increasingly arid toward the interior on the Deccan Plateau (Fig. 1b). The natural vegetation reflects this gradual decrease in moisture: the headwaters on the Deccan are dominated by C_4-plant thornbush savannah adapted to dry conditions, whereas C_3-flora (deciduous forests) are dominant in the Eastern Ghats (Asouti and Fuller, 2008; Fig. 1c).

Sediments transported by the Godavari are sourced from two major geological units (Bikshamaiah and Subramanian, 1980). The upper river basin developed on the Deccan Traps, a large igneous province consisting of relatively young flood basalts (Cretaceous to early Neogene) that largely span the Deccan Plateau. The lower river basin developed over old Proterozoic to Archaean crystalline igneous/metamorphic rocks of the Indian Craton (Fig. 1d). The relatively young Deccan basalts retain a highly radiogenic mantle-derived Nd isotope composition (ɛNd of +1±5) while the old continental crust of the Indian Craton has a relatively unradiogenic isotopic composition (ɛNd of -35±8), yielding a sharp contrast between geological end-members. Thus, the sediment provenance for the Godavari sediments can be deduced from the Nd isotopic signatures of the detrital inorganic fraction in our core because the Nd signal remains unmodified through bedrock weathering processes (McLennan and Hemming, 1992; DePaolo, 1988).

Black soils cover the Deccan Plateau whereas red soils are generally typical for the Eastern Ghats (Bhattacharyya et al., 2003; Fig. 1d). Although both types of soils have been affected by landuse since prehistorical times, the black soils of the arid to semi-arid Deccan appear to be the most degraded at present (Singh et al., 1992). Intense soil erosion within the basin is reflected by the inordinately large sediment load of the Godavari relative to its water discharge (Bikshamaiah and Subramanian, 1980). In contrast to the dynamic Himalayan rivers of the Indo-Gangetic alluvial plain, Godavari and its tributaries are incised in rock or alluvium and have relatively stable sandy channels. As for other rivers affected by storms (Edwards and Owens, 1991; Hilton et al., 2008), extreme rainfall events are disproportionately important for erosion in the Godavari watershed and in subsequent transport of sediments to the ocean (Kale, 2003).
Given their incised morphology, shifts in channel position in response to floods are however rare above the Godavari delta (Kale, 2002). Floodplains are limited in extent (2% of the basin; Bikshamaiah and Subramanian, 1980), and loss of sediments to overbank deposition is minor (Kale, 2002). Therefore storage is minimal in these intermediate alluvial reservoirs that normally would increase the residence time of sediments, including particulate organic carbon.

Once reaching the Bay of Bengal, sediment delivered by the Godavari has constructed a large Holocene delta (Rao et al. 2005). Offshore from the Godavari mouth, a persistent sediment plume extends over 300 km during the monsoon season when over 90% of the fluvial sediment is discharged (Sridhar et al., 2008). Because the shelf in front of the delta is unusually narrow (i.e., under 10 km at our core location) copious sediment deposition takes place directly on the continental slope, resulting in sediment accumulation rates as high as 250 cm/kyr (Ponton et al., 2012). This relatively simple sedimentary regime of the Godavari system in combination with the monsoon-dominated climatology and the simple geology of the Godavari basin allows for relatively straightforward interpretation of sediment sources and transfer processes. The monsoon washload is rapidly and directly delivered to the continental margin without significant trapping in intermediate depocenters along the river. As the suspended load makes up over 95% of the total sediment transported by the Godavari (Syvitski and Saito, 2007), the washload-derived terrestrial proxies are representative for the production of fine-grained sediment in the basin. Potential contributions from resuspension of shelf sediments cannot be excluded but are likely minor due to the narrowness of the shelf; furthermore, given the large sedimentation rates on the shelf itself (Forsberg et al., 2007), the resuspended sediment is expected to be quasi-contemporaneous with sediments arriving on the slope directly from the river plume.

3. Hydroclimate in the Core Monsoon Zone

We have previously reconstructed the Holocene paleoclimate using the same sediment core discussed herein (Ponton et al., 2012; Zorzi et al., 2015). Terrestrial reconstructions were based on the carbon isotopic compositions of higher plant leaf-wax biomarkers (i.e., long-chain n-alkanoic acids C_{26-32}) and pollen, whereas contemporaneous sea surface paleoclimatographic conditions in front of the Godavari delta came from the oxygen isotopic composition of planktonic foraminifer *Globigerinoides ruber*. Sedimentary leaf waxes provide an integrated δ^{13}C record of the flora in the CMZ that document an increase in aridity-adapted vegetation (C_{4} plants) after the monsoon maximum in the early Holocene (Ponton et al., 2012; Fig. 2). The overall trend of the δ^{13}C leaf wax record agrees with the view that the seasonality of Northern Hemisphere insolation (Ponton et al., 2012) led to progressively weaker monsoons over the Holocene. However, two clear aridification steps are evident: between ~5000 and 4500 years ago, and ~1,700 years ago (Fig. 2). Pollen from the same core (Zorzi et al., 2015) reinforce these conclusions:
coastal forest and mangrove pollen (Fig. 2) that are typical for the more humid coastal regions of the Eastern Ghats and Godavari delta declined over the Holocene.

Dryness-adapted thornbush pollen from the Deccan Plateau increased substantially after the second aridification step ~1700 years ago, overlapping well with the maximum contribution of C₄ plant-derived leaf waxes (see Zorzi et al., 2015). For the same time interval, the ice volume-corrected oxygen isotopic composition of planktonic foraminifer Globigerinoides ruber documented a series of low values interpreted as high salinity events at the Godavari mouths (see Ponton et al., 2012). Together these continental and oceanic records suggest that the CMZ aridification intensified in the latest Holocene via a series of short drier episodes (Ponton et al., 2012). This interpretation is reinforced by speleothem-derived records from central and northern India for the past thousand years (Sinha et al., 2011), and the overall evolution of the CMZ hydroclimate as seen from our core is supported by local reconstructions from the Lonar crater lake in central India (Prasad et al., 2014; Sarkar et al., 2015) and other records from the larger Indian monsoon domain (Gupta et al., 2003; Fleitmann et al., 2003; Prasad and Enzel, 2006; Berkelhammer et al., 2012; Dixit et al., 2014b).

4. Erosion in the Godavari Basin

The Holocene sediment flux at our core location (Fig. 2) is representative for the Godavari continental slope (Mazumdar et al., 2009; Ramprasad et al. 2011; Joshi et al., 2014; Usapkar et al., 2016) and is driven by changes in the siliciclastic sedimentation rate as dilution by biogenic carbonates is less than 5% (Johnson et al., 2014). Despite a lower sea level at the time, the flux was relatively small in the early Holocene (~25 g/cm²/kyr) but began to increase after 6000 years ago (~40 g/cm²/kyr), as soon as the monsoon started to decline but well before the adoption of Neolithic agriculture and settlement of the savannah zone of the central peninsula (~4500 years ago; Fuller, 2011). Between 4000 and 3500 years ago permanent agricultural settlements spread throughout the Deccan Plateau. The associated small-scale metallurgy (copper-working) requiring firewood together with the agricultural intensification probably also affected erosion via widespread deployment of two cropping seasons (Kajale, 1988; Fuller and Madella, 2001). As the climate remained arid, sediment fluxes stayed high despite a phase of agricultural abandonment and depopulation between ~3,200 and 2,900 years ago (Dhavalikar, 1984; Roberts et al., 2016).

A further step increase in the sediment flux (~90 g/cm²/kyr on average) occurred after ~3000 years ago, this time with no apparent concomitant change in climate. The Nd isotopic signal points to an increase in the Deccan sedimentary output at the time, after a muted variability earlier in the Holocene when the Indian Craton consistently provided ~50-60% of the sediments (Fig. 2; see Supplementary Materials). New improvements in agricultural technology became widespread in the Deccan Plateau, including use of iron
agricultural tools (Mohanty and Selvakumar, 2001) that required firewood-fuelled
smelting Fuller, 2008). A new phase of agricultural settlement began in the middle
Godavari basin (eastern Maharashtra) between ~3000 to ~2800 years ago (Brubaker
2000). However, the largest boost in sediment flux occurred after ~2000 years ago, when
the monsoon reached its driest phase and when further increases in population occurred
resulting in the founding of towns and the first cities of the region at the beginning of the
Historic period (Allchin 1995; Parabrahma Sastry 2003). This doubling in sediment flux
relative to the early Holocene values involved a basin-wide increase in erosion. The
contribution from the Deccan Plateau, although at its maximum according to the Nd
isotope mixing model, only accounts for a 15% shift in sediment source (Fig. 2).

Overall, watersheds with high precipitation have higher discharge and discharge
magnitude is considered a primary regulator for sediment and carbon erosional fluxes to
the ocean (e.g., Summerfield and Hulton, 1994; Ludwig et al., 1996; Galy et al., 2015).
However, our Godavari record shows that erosional output is maximized by aridity
because significant rain and seasonal floods still occur during the summer monsoon
season (Mujumdar et al., 1970; Kale, 2003). Aridification and/or agricultural expansion
lead to changes in vegetation type (i.e., forest decrease in favour of savannah) and cover
(i.e., shrinking of naturally vegetated lands in favour of agricultural and/or degrading arid
lands) that exacerbate soil erosion (i.e., Langbein and Schum, 1958; Dunne, 1979;
Walling and Webb, 1983; Istanbulluoglu and Bras, 2005; Vanacker et al., 2007; Collins
and Bras, 2008).

5. Carbon Export from the Godavari Basin

The terrigenous organic carbon exported by rivers consists of a mixture of dissolved and
particulate components derived from contemporary vegetation and of carbon stored in
bedrock, soils and fluvial sediments that may be significantly pre-aged (Smittenberg et
al., 2006; Galy and Eglinton, 2011; Feng et al., 2013). On the Godavari slope, the
terrigenous fraction dominates the total organic carbon (TOC) in marine sediments
(Johnson et al., 2014). In agreement with this, TOC radiocarbon ages in our core have
been previously found to be remarkably similar to co-located ages of the strictly
terrigenous higher plant leaf wax fraction (Ponton, 2012). This age similarity also
excludes interferences from within-river biological productivity (e.g., Eglinton and
Hamilton, 1967; Eglinton and Eglinton, 2008). To assess the variability of the terrigenous
carbon age exported by Godavari River based on this understanding we used high
resolution TOC radiocarbon measurements to calculate radiocarbon age offsets relative to
the atmosphere (Soulet et al., 2016; see Supplementary Materials). Over the Holocene,
these biospheric organic carbon radiocarbon age offsets in our core mirror the history of
erosion in the basin (Fig. 2).
As a first order observation, TOC ages (Fig. 2 and Supplementary Materials) are significantly older (~200 to 2000 $^{14}$C years) than their depositional age in our Godavari core. Before 5000 years ago the bulk organic carbon radiocarbon age offset were ~600 $^{14}$C years old on average. In contrast, the highly erosional regime under both climatic and early human pressure in the late Holocene led to the export of significantly older carbon from the terrestrial biosphere, i.e., ~1300 $^{14}$C on average. This increase in radiocarbon age offset occurred largely during the two aridification steps identified by Ponton et al. (2012): more abruptly between ~5000 and 4500 years ago and more gradually after ~1700 years ago (Fig. 2).

In the absence of significant storage in alluvial sediments in the Godavari catchment, several processes can explain the doubling in age offset over the Holocene: an overall slowing of soil carbon turnover in the drying climate of central India, a decrease in TOC contribution from contemporaneous vegetation relative to older (pre-aged) soil carbon input and/or deeper exhumation of soils contributing increasingly older carbon. Given the drastic changes in vegetation cover and increase in erosion in the Godavari basin, a decrease in soil turnover is unlikely during the Holocene aridification process (Carvalhais et al. 2014). In turn, the good agreement between the pollen and leaf-wax $\delta^{13}$C records in our core (Ponton et al., 2012; Zorzi et al., 2015) with independent monsoon reconstructions suggests sustained delivery of recently fixed biospheric organic carbon to the delta. Thus, the doubling in age offset over the Holocene is best explained by increasing contributions from an older soil component, which could only come through deeper erosion. Because the age of soil organic carbon in soil profiles increases with depth (Trumbore, 2009), older mixtures imply a deeper soil erosion, whether uniform, or through gullies, which are common especially on the Deccan Plateau (Kothyari, 1996).

6. The Monsoon Erosional Pump

Overall, these multiple lines of evidence indicate that soil erosion in the CMZ, as integrated by the Godavari River, increased throughout the basin immediately as climate began to dry at the end of mid Holocene, and was further enhanced by Deccan agricultural activities in the late Holocene. The likely mechanism for this is the extreme seasonal distribution of the rainfall that characterizes the monsoon (Wang and Ding, 2008), which promoted erosion on the more sparsely vegetated landscapes (Molnar, 2001; DiBiase and Whipple, 2011; Plink-Bjorklund, 2015). Our findings thus point to a veritable “monsoon erosional pump” that accelerates during minimum landcover conditions when the protective role of vegetation is reduced, whether naturally or by humans. The volume of total eroded sediments since the mid Holocene must have been considerable as the continental margin growth accelerated with the shelf edge aggrading ~80 meters in the last ~2000 years alone (Forsberg et al., 2007).
The monsoon erosional pump must have been active before the Holocene as well, affecting the transfer of terrigenous sediment, solutes and carbon from land to the ocean. The beat of monsoon precipitation on orbital timescales is not well constrained but considered to be modulated by at a combination of precession and obliquity frequencies based on monsoon wind reconstructions (e.g., Clemens and Prell, 2003). Such complex variability did not inevitably follow the sea level cyclicity (e.g., Goodbred and Kuehl, 2000), which is usually assumed to control most of the sediment transfer from land to the deep ocean (see Blum and Hattier-Womack, 2009 and references therein). Thus untangling the effects of the monsoon is difficult especially during the Quaternary (e.g., Phillips et al., 2014), but may be easier to discern earlier when the sea level change magnitude was reduced. Landcover effects are also less likely to occur in the upper basins of Himalayan monsoonal rivers where elevation (i.e., temperature), orographic precipitation as well as other sources of water such as snow and glaciers promote ecological stability (Galy et al., 2008a; but see Olen et al., 2016 for an alternative viewpoint). However, the erosional pump should still be active in their lower basins where aridity controls vegetation type and cover (e.g., Galy et al. 2008b).

Recent coupled erosion-carbon cycling modeling suggests that long-term anthropogenic acceleration of erosion has had a significant impact on the global carbon cycle by intensifying the burial of terrigenous carbon (Wang et al., 2017). Whereas the monsoon domain only covers ~15% of the Earth’s surface (Hsu et al., 2011), it used to export to the ocean ~70% of the sediment load from the Earth’s largest rivers (see Syvitski and Saito, 2007 for a compilation for pre-damming conditions). Therefore, we suspect that the cumulative effect of the monsoon erosional pump on the carbon budget was substantial in augmenting the burial of terrigenous carbon during the Holocene and needs to be estimated for inclusion in assessments of the net soil–atmosphere carbon exchange.
