**Abstract.** Sediment mass conservation is a key factor that constrains river morphodynamic processes. In most models of river morphodynamics, sediment mass conservation is described by the Exner equation, which may take various forms depending on the problem in question. One of the most widely used forms of the Exner equation is the flux-based formulation, in which the conservation of bed material is related to the streamwise gradient of the sediment transport rate. An alternative form of the Exner equation, however, is the entrainment-based formulation, in which the conservation of bed material is related to the difference between the entrainment rate of bed sediment into suspension and the deposition rate of suspended sediment onto the bed. Here we represent the flux form in terms of the local capacity sediment transport rate, and the entrainment form in terms of the local capacity entrainment rate. In the flux form, sediment transport is a function of local hydraulic conditions. However, the entrainment form does not require this constraint: only the rate of entrainment into suspension is in local equilibrium with hydraulic conditions, and the sediment transport rate itself may lag in space and time behind the changing flow conditions. In modeling the fine-grained Lower Yellow River, it is usual to treat sediment conservation in terms of an entrainment (nonequilibrium) form rather than a flux (equilibrium) form, in consideration of the condition that fine-grained sediment may be entrained at one place but deposit only at some distant location downstream. However, the differences in prediction between the two formulations have not been comprehensively studied to date. Here we study this problem by comparing the results predicted by both the flux form and the entrainment form of the Exner equation, under conditions simplified from the Lower Yellow River (i.e. a significant reduction of sediment supply after the closure of the Xiaolangdi Dam). We use a one-dimensional morphodynamic model and sediment transport equations specifically adapted for the Lower Yellow River. We find that in a treatment of a 200 km reach using a single characteristic bed sediment size, there is little difference between the two forms since the corresponding adaptation length is relatively small. However, a consideration of sediment mixtures shows that the two forms give very different patterns of grain sorting: clear kinematic waves occur in the

34 flux form but are diffused out in the entrainment form. Both numerical simulation and mathematical analysis show that the  
35 morphodynamic processes predicted by the entrainment form are sensitive to sediment fall velocity. We suggest that the  
36 entrainment form of the Exner equation might be required when the sorting process of fine-grained sediment is studied,  
37 especially when considering relatively short time scales.

## 38 **1. Introduction**

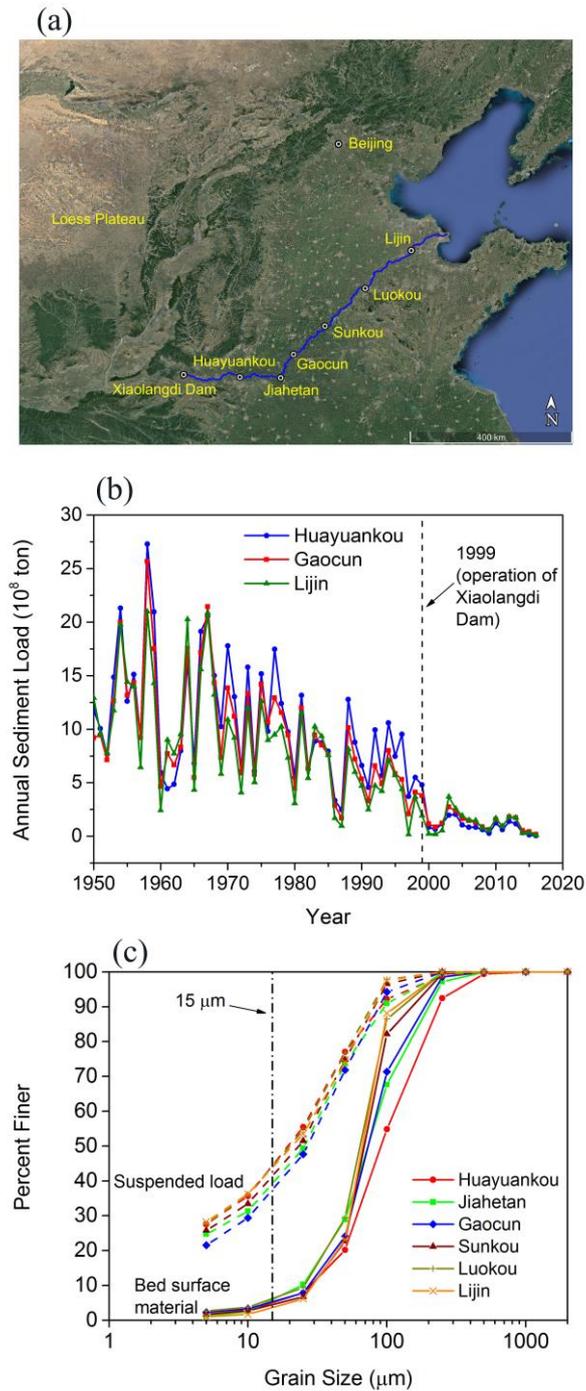

39 Models of river morphodynamics often consist of three elements: (1) a treatment of flow hydraulics; (2) a formulation  
40 relating sediment transport to flow hydraulics; and (3) a description of sediment conservation. In the case of unidirectional  
41 river flow, the Exner equation of sediment conservation has usually been described in terms of a flux-based form in which  
42 temporal bed elevation change is related to the streamwise gradient of the sediment transport rate. That is, bed elevation change  
43 is related to  $\partial q_s / \partial x$ , where  $q_s$  is the total volumetric sediment transport rate per unit width and  $x$  is the streamwise coordinate  
44 (Exner, 1920; Parker et al., 2004). This formulation is also referred to as the equilibrium formulation, since it considers  
45 sediment transport to be at local equilibrium, i.e.  $q_s$  equals its sediment transport capacity  $q_{se}$ , as defined by the sediment  
46 transport rate associated with local hydraulic conditions (e.g. bed shear stress, flow velocity, stream power, etc.), regardless of  
47 the variation of flow conditions. Under this assumption, sediment transport relations developed under equilibrium flow  
48 conditions (e.g., Meyer-Peter and Müller, 1948; Engelund and Hansen, 1967; Brownlie, 1981) can be incorporated directly in  
49 such a formulation to calculate  $q_s$ , which is related to one or more flow parameters such as bed shear stress.

50 An alternative formulation, however, is available in terms of an entrainment-based form of the Exner equation, in  
51 which bed elevation variation is related to the difference between the entrainment rate of bed sediment into the flow and the  
52 deposition rate of sediment on the bed (Parker, 2004). The basic idea of the entrainment formulation can be traced back to  
53 Einstein's (1937) pioneering work on bedload transport, and has been developed since then by numerous researchers so as to  
54 treat either bedload or suspended load (Tsujiimoto, 1978; Armanini and Di Silvio, 1988; Parker et al., 2000; Wu and Wang,  
55 2008; Guan et al., 2015). Such a formulation differs from the flux formulation in that the flux formulation is based on the local  
56 capacity sediment transport rate whereas the entrainment formulation is based on the local capacity entrainment rate into  
57 suspension. In the entrainment form, the difference between the local entrainment rate from the bed and the local deposition  
58 rate onto the bed determines the rate of bed aggradation/degradation, and concomitantly the rate of loss/gain of sediment in  
59 motion in the water column. Therefore, the sediment transport rate is no longer assumed to be in an equilibrium transport state,  
60 but may exhibit lags in space and time after changing flow conditions. The entrainment formulation is also referred to as the  
61 nonequilibrium formulation (Armanini and Di Silvio, 1988; Wu and Wang, 2008; Zhang et al., 2013).

62 To describe the lag effects between sediment transport and flow conditions, the concept of an adaptation length/time  
63 is widely applied. This length/time characterizes the distance/time for sediment transport to reach its equilibrium state (i.e.,  
64 transport capacity). Using the concept of the adaptation length, the entrainment form of the Exner equation can be recast into  
65 a first-order "reaction" equation, in which the deformation term is related to the difference between the actual and equilibrium

66 sediment transport rates, as mediated by an adaptation length (which can also be recast as an adaptation time) (Bell and  
67 Sutherland, 1983; Armanini and Di Silvio, 1988; Wu and Wang, 2008; Minh Duc and Rodi, 2008; El kadi Abderrezzak and  
68 Paquier, 2009). The adaptation length is thus an important parameter for bed evolution under nonequilibrium sediment  
69 transport conditions, and various estimates have been proposed. For suspended load, the adaptation length is typically  
70 calculated as a function of flow depth, flow velocity and sediment fall velocity (Armanini and Di Silvio, 1988; Wu et al., 2004;  
71 Wu and Wang, 2008; Dorrell and Hogg, 2012; Zhang et al., 2013). The adaptation length of bedload, on the other hand, has  
72 been related to a wide range of parameters, including the sediment grain size (Armanini and Di Silvio, 1988), the saltation step  
73 length (Phillips and Sutherland, 1989), the dimensions of particle diffusivity (Bohorquez and Ancy, 2016), the length of dunes  
74 (Wu et al., 2004), and the magnitude of a scour hole formed downstream of an inerodible reach (Bell and Sutherland, 1983).  
75 For simplicity, the adaptation length can also be specified as a calibration parameter in river morphodynamic models (El kadi  
76 Abderrezzak and Paquier, 2009; Zhang and Duan, 2011). Nonetheless, no comprehensive definition of adaptation length exists.

77 In this paper we apply the two forms of the Exner equation mentioned above to the Lower Yellow River (LYR) in  
78 China. The LYR describes the river section between Tiexie and the river mouth, and has a total length of about 800 km. Figure  
79 1(a) shows a sketch of the LYR along with 6 major gauging stations and the Xiaolangdi Dam, which is 26 km upstream of  
80 Tiexie. The LYR has an exceptionally high sediment concentration (Ma et al., 2017), historically exporting more than 1 Gt of  
81 sediment per year with only 49 billion tons of water, leading to a sediment concentration an order of magnitude higher than  
82 most other large lowland rivers worldwide (Milliman and Meade, 1983; Ma et al., 2017; Naito et al., accepted subject to  
83 revision). However, the LYR has seen a substantial reduction in its sediment load in recent decades, especially since the  
84 operation of Xiaolangdi Dam in 1999 (Fig. 1(b)), because most of its sediment load is derived from the Loess Plateau which  
85 is upstream of the reservoir (Wang et al., 2016; Naito et al., accepted subject to revision). Finally, the bed surface material of  
86 the LYR is very fine, ranging as low as 15  $\mu\text{m}$ . This is much finer than the conventional cutoff of washload (62.5  $\mu\text{m}$ ) employed  
87 for sediment transport in most sand-bed rivers (National Research Council, 2007; Ma et al., 2017).

When modeling the high-concentration and fine-grained LYR, it is common to treat sediment conservation in terms of an entrainment-based rather than a flux-based formulation. This is because many Chinese researchers view the entrainment formulation as more physically based, as it is capable of describing the behavior of fine-grained sediment, which when entrained at one place may be deposited at some distant location downstream (Zhang et al., 2001; Ni et al., 2004; Cao et al., 2006; He et al., 2012; Guo et al., 2008). However, the entrainment formulation is more computationally expensive and more complex to implement. In so far as the differences in prediction between the two formulations do not appear to have been studied in a systematic way, here we pose our central questions. Under what conditions is it valid to use the entrainment form of the Exner equation, and under what conditions may the flux form be used? Or more specifically, which form of the Exner equation is most suitable for the LYR?

Here we study this problem by comparing the results of flux-based and entrainment-based morphodynamics under conditions typical of the LYR. The organization of this paper is as follows. The numerical model is described in Section 2. In Section 3, the model is implemented to predict the morphodynamics of the LYR with a sudden reduction of sediment supply, which serves to mimic the effect of Xiaolangdi Dam. We find that the two forms of the Exner equation give similar predictions in the case of uniform sediment, but show different sorting patterns in the case of sediment mixtures. In Section 4, we conduct a mathematical analysis to explain the results in Section 3, and more specifically we quantify the effects of varied sediment fall velocity in the simulations. Finally, we summarize our conclusions in Section 5.

**2. Model formulation**

In this paper, we present a one-dimensional morphodynamic model for the Lower Yellow River. The fully unsteady Saint Venant Equations are implemented for the hydraulic calculation. Both the flux form and the entrainment form of the Exner equation are implemented in the model for sediment mass conservation. For each form of Exner equation, we consider both the cases of uniform sediment (bed material characterized by a single grain size) and sediment mixtures. Since the sediment is very fine in the LYR, the component of the load that is bedload is likely negligible (e.g. Ma et al., 2017), so that we consider only the transport of suspended load. Considering the fact that most accepted sediment transport relations (e.g., the Engelund and Hansen (1967) relation) underpredict the sediment transport rate of the LYR by an order of magnitude or more (Ma et al., 2017), in our model we implement two recently developed generalized versions of the Engelund-Hansen relation which are based on data from the LYR. These are the version of Ma et al. (2017) for uniform sediment, and the version of Naito et al. (accepted subject to revision) for sediment mixtures. In cases considering sediment mixtures, we also implement the method of Viparelli et al. (2010) to store and access bed stratigraphy as the bed aggrades and degrades.

Since the aim of this paper is to compare the two formulations of the Exner equation in context of the LYR, rather than reproduce site-specific morphodynamic processes of the LYR, some additional simplifications are introduced to the model to facilitate comparison. The channel is simplified to be a constant-width rectangular channel, and bank (sidewall) effects and

124 floodplain interactions are not considered. The channel bed is assumed to be an infinitely deep supplier of erodible sediment  
 125 with no exposed bedrock, which is justifiable because the LYR is fully alluvial, and has been aggrading for thousands of years,  
 126 as copiously documented in Chinese history. Finally, water and sediment (of each grain size range) are fed into the upstream  
 127 boundary at a specified rate, and at the downstream end of the channel we specify a fixed bed elevation along with a normal  
 128 flow depth. These restrictions could be easily relaxed so as to incorporate site-specific complexities of the Yellow River.  
 129 Because of the severe aggradation of the LYR developed before the Xiaolangdi Dam operation, the LYR is famous for its  
 130 hanging bed (i.e. bed elevated well above the floodplain) and no major tributaries need be considered in the simulation.

## 131 2.1 Flow hydraulics

132 Flow hydraulics in a rectangular channel is described by the following 1D Saint Venant equations, which consider  
 133 fluid mass and momentum conservation,

$$134 \frac{1}{I_f} \frac{\partial h}{\partial t} + \frac{\partial q_w}{\partial x} = 0 \quad (1)$$

$$135 \frac{1}{I_f} \frac{\partial q_w}{\partial t} + \frac{\partial}{\partial x} \left( \frac{q_w^2}{h} + \frac{1}{2} gh^2 \right) = ghS - C_f u^2 \quad (2)$$

$$136 C_f = C_z^{-2} \quad (3)$$

137 where  $t$  is time,  $h$  is water depth,  $q_w$  is flow discharge per unit width,  $g$  is gravitational acceleration,  $S$  is bed slope,  $u$  is depth-  
 138 averaged flow velocity,  $C_f$  is dimensionless bed resistance coefficient, and  $C_z$  is the dimensionless Chezy resistance coefficient.  
 139 In our model, the fully unsteady 1D Saint Venant equations are solved using a Godunov type scheme with the HLL (Harten-  
 140 Lax-van Leer) approximate Riemann solver (Harten et al., 1983; Toro, 2001), which can effectively capture discontinuities in  
 141 unsteady and nonuniform open channel flows.

142 In this paper, the full flood hydrograph of the LYR is replaced by a flood intermittency factor  $I_f$  (Paola et al., 1992;  
 143 Parker, 2004). According to this definition, the river is assumed to be at low flow and not transporting significant amounts of  
 144 sediment for time fraction  $1 - I_f$ ; and is in flood at constant discharge and active morphodynamically for time fraction  $I_f$ . In the  
 145 long term, the relation between the flood time scale  $t_f$  and the actual time scale  $t$  is  $t_f = I_f t$ . With the consideration that a river  
 146 is in flood only for a fraction of time, here we introduce  $I_f$  into the time derivative of all governing equations, so that the flood  
 147 time scale  $t_f$  is implemented in the simulation. This notwithstanding, the results we exhibit later in this paper are all cast in  
 148 terms of actual time scale  $t$ . Full hydrographs are considered in the Supplement.

149 **2.2 Flux form of the Exner equation**

150 When dealing with uniform sediment, the flux form of the Exner equation can be written as,

151 
$$\frac{1}{I_f} (1 - \lambda_p) \frac{\partial z_b}{\partial t} = - \frac{\partial q_s}{\partial x} \quad (4)$$

152 where  $\lambda_p$  is the porosity of the bed deposit, and  $z_b$  is bed elevation. Sediment transport is regarded to be in a quasi-equilibrium  
 153 state, so that the sediment transport rate per unit width  $q_s$  equals the equilibrium (capacity) sediment transport rate per unit  
 154 width  $q_{se}$ .

155 When considering sediment mixtures, an active layer formulation (Hirano, 1971; Parker, 2004) is incorporated in the  
 156 flux-based Exner equation, so that the evolution of both bed elevation and surface grain size distribution can be considered. In  
 157 this formulation, the river bed is divided into a well-mixed upper active layer and a lower substrate with vertical stratigraphic  
 158 variations. The upper active layer therefore represents the volume of sediment that interacts directly with suspended load  
 159 transport, and also exchanges with the substrate as the bed aggrades and degrades. Discretizing the grain size distribution into  
 160  $n$  ranges, the mass conservation relation for each grain size range can be written as,

161 
$$\frac{1}{I_f} (1 - \lambda_p) \left[ f_{ii} \frac{\partial}{\partial t} (z_b - L_a) + \frac{\partial}{\partial t} (F_i L_a) \right] = - \frac{\partial q_{si}}{\partial x} \quad (5)$$

162 where  $q_{si}$  is volumetric sediment transport rate per unit width of the  $i$ -th grain size range ( taken to be equal to its equilibrium  
 163 value  $q_{sei}$  in the flux formulation),  $F_i$  is the volumetric fraction of surface material in the  $i$ -th grain size range;  $f_{ii}$  is volumetric  
 164 fraction of material in the  $i$ -th grain size range exchanged across the surface-substrate interface as the bed aggrades or degrades,  
 165 and  $L_a$  is the thickness of active layer. For bedform-dominated sand-bed rivers,  $L_a$  is often related to the height of dunes (Blom,  
 166 2008) so that the vertical sorting processes due to bedform migration can be considered. In this paper, a constant value of  $L_a$   
 167 is implemented in the simulation.

168 Summing Eq. (5) over all grain size ranges, one can find that the governing equation for bed elevation in case of  
 169 sediment mixtures is the same as Eq. (4) upon replacing  $q_s$  with  $q_{sT} = \sum q_{si}$ , where  $q_{sT}$  denotes the total sediment transport rate  
 170 per unit width summed over all size ranges. Reducing Eq. (5) with Eq. (4) we get,

171 
$$\frac{1}{I_f} (1 - \lambda_p) \left[ L_a \frac{\partial F_i}{\partial t} + (F_i - f_{ii}) \frac{\partial L_a}{\partial t} \right] = f_{ii} \frac{\partial q_{sT}}{\partial x} - \frac{\partial q_{si}}{\partial x} \quad (6)$$

172 Therefore, in the flux formulation Eqs. (4) and (6) are implemented as governing equations for sediment mixtures,  
 173 with Eq. (4) describing the evolution of bed elevation and Eq. (6) describing the evolution of surface grain size distribution.  
 174 The exchange fractions  $f_{ii}$  between the active layer and the substrate are calculated using the following closure relation,

$$f_{ii} = \begin{cases} f_i|_{z_b-L_a} & \frac{\partial(z_b - L_a)}{\partial t} < 0 \\ \alpha F_i + (1-\alpha) p_{si} & \frac{\partial(z_b - L_a)}{\partial t} > 0 \end{cases} \quad (7)$$

That is, the substrate is transferred into the active layer during degradation, and a mixture of suspended load and active layer material is transferred into substrate during aggradation. In Eq. (7),  $f_i|_{z_b-L_a}$  is the volumetric fraction of substrate material just beneath the interface,  $p_{si} = q_{si}/q_{sT}$  is the fraction of bed material load in the  $i$ -th grain size range, and  $\alpha$  is a specified parameter between 0 and 1. The formulation is adapted from Hoey and Ferguson (1994) and Toro-Escobar et al. (1996), who originally used it for bedload. In this paper, a value of 0.5 is specified for  $\alpha$ .

The method of Viparelli et al. (2010) is applied in our model to store substrate stratigraphy and provide information for  $f_i|_{z_b-L_a}$  (i.e., the topmost sublayer in Viparelli et al., 2010). The reader can refer to the original reference of Viparelli et al. (2010) for more details, or refer to An et al. (2017) for a concise description as to how to implement this method in a morphodynamic model. When solving the flux form of the Exner equation, a first-order upwinded scheme is implemented to discretize the spatial derivatives, and a first-order explicit scheme is implemented to discretize the temporal derivatives.

### 2.3 Entrainment form of the Exner equation

The entrainment-based Exner equation for uniform sediment is,

$$\frac{1}{I_f} (1 - \lambda_p) \frac{\partial z_b}{\partial t} = -v_s (E - r_0 C) \quad (8)$$

In Eq. (8),  $v_s$  is the fall velocity of sediment particles;  $E$  is the dimensionless entrainment rate of sediment normalized by sediment fall velocity;  $C$  is the depth-flux-averaged volume sediment concentration; and  $r_0 = c_b/C$  is the recovery coefficient of suspended load which denotes the ratio between the near-bed sediment concentration  $c_b$  and the flux-averaged sediment concentration  $C$ . By definition,  $r_0$  is related to the concentration profile of suspended load, and is expected to be no less than unity in cases appropriate for a depth-averaged shallow-water treatment of flow and morphodynamics. Therefore, the first term on the right hand side of Eq. (8), i.e.  $v_s E$ , denotes the sediment entrainment rate per unit area; the second term on the right hand side of Eq. (8), i.e.  $v_s r_0 C$ , denotes the sediment deposition rate per unit area.

For the sediment fall velocity  $v_s$ , we compare two widely used relations: the relation of Dietrich (1982), and the relation of Ferguson and Church (2004). Results show that these two relations give almost the same fall velocity for bed material load of the LYR, whose grain sizes typically fall in the range of 15  $\mu\text{m}$  to 500  $\mu\text{m}$ . Therefore, only the relation of

199 Dietrich (1982) is implemented in our simulations in this paper. Readers can refer to Section S1 of the Supplement for more  
 200 details.

201 In the entrainment formulation the sediment transport rate  $q_s$  is not necessarily in its equilibrium state, but the  
 202 dimensionless entrainment rate  $E$  is taken to be to be at capacity. The sediment transport rate  $q_s$  is calculated according to the  
 203 following continuity relation,

$$204 \quad q_s = huC \quad (9)$$

205 For the dimensionless entrainment rate  $E$ , we assume that sediment transport reaches its equilibrium state ( $q_s = q_{se}$ ) when the  
 206 sediment deposition rate and the sediment entrainment rate balance each other ( $r_0C = E$ ). Therefore,  $E$  can be back-calculated  
 207 from  $q_{se}$  as,

$$208 \quad E = r_0 \frac{q_{se}}{q_w} \quad (10)$$

209 For the depth-flux-averaged sediment concentration  $C$ , another equation is implemented describing the conservation of  
 210 suspended sediment in the water column,

$$211 \quad \frac{1}{I_f} \frac{\partial(hC)}{\partial t} + \frac{\partial(huC)}{\partial x} = v_s (E - r_0C) \quad (11)$$

212 The entrainment-form Exner equation for sediment mixtures also uses the active layer formulation described in  
 213 Section 2.2. Mass conservation of each grain size range can be written as,

$$214 \quad \frac{1}{I_f} (1 - \lambda_p) \left[ f_{ii} \frac{\partial}{\partial t} (z_b - L_a) + \frac{\partial}{\partial t} (F_i L_a) \right] = -v_{si} (E_i - r_{0i} C_i) \quad (12)$$

$$215 \quad E_i = r_{0i} \frac{q_{sei}}{q_w} \quad (13)$$

216 where the subscript  $i$  denotes the  $i$ -th size range of sediment grain size.

217 Summing Eq. (12) over all grain size ranges, we get the governing equation for bed elevation,

$$218 \quad \frac{1}{I_f} (1 - \lambda_p) \frac{\partial z_b}{\partial t} = - \sum_{j=1}^n v_{sj} (E_j - r_{0j} C_j) \quad (14)$$

219 Reducing Eq. (12) with Eq. (14) we get the governing equation for surface fraction  $F_i$ ,

$$220 \quad \frac{1}{I_f} (1 - \lambda_p) \left[ L_a \frac{\partial F_i}{\partial t} + (F_i - f_{li}) \frac{\partial L_a}{\partial t} \right] = f_{li} \sum_{j=1}^n v_{sj} (E_j - r_{0j} C_j) - v_{si} (E_i - r_{0i} C_i) \quad (15)$$

221 The governing equation for the sediment concentration of each grain size  $C_i$  can be written as,

$$222 \quad \frac{1}{I_f} \frac{\partial (hC_i)}{\partial t} + \frac{\partial (huC_i)}{\partial x} = v_{si} (E_i - r_{0i} C_i) \quad (16)$$

223 and the sediment transport rate per unit width for the  $i$ -th size range  $q_{si}$  obeys the following continuity relation,

$$224 \quad q_{si} = huC_i \quad (17)$$

225 In the entrainment formulation, the closure relation for  $f_{li}$  is the same as that used in the flux formulation (i.e., Eq.  
226 (7)), and the substrate stratigraphy is also stored and accessed using the method of Viparelli et al. (2010). When discretizing  
227 the entrainment form of the Exner equation, a first-order upwinded scheme is implemented for the spatial derivatives, and a  
228 first-order explicit scheme is implemented for the temporal derivatives.

## 229 2.4 Sediment transport relation

### 230 2.4.1 Uniform sediment

231 To close the Exner equations described in Sections 2.2 and 2.3, equations for equilibrium sediment transport rate  $q_{se}$   
232 ( $q_{sei}$ ) are still needed. For the simulations using uniform sediment, we implement the generalized Engelund-Hansen relation  
233 proposed by Ma et al. (2017). This equation is based on the data from LYR and can be written in the following dimensionless  
234 form,

$$235 \quad q_s^* = \frac{\alpha_s}{C_f} (\tau^*)^{n_s} \quad (18)$$

236 where  $q_s^*$  is dimensionless sediment transport rate per unit width (i.e., the Einstein number), and  $\tau^*$  is dimensionless shear  
237 stress (i.e., the Shields number). They are defined as,

$$238 \quad q_s^* = \frac{q_{se}}{\sqrt{RgDD}} \quad (19)$$

$$239 \quad \tau^* = \frac{\tau_b}{\rho RgD} \quad (20)$$

$$240 \quad \tau_b = \rho C_f u^2 \quad (21)$$

241 where  $D$  is the characteristic grain size of the bed sediment (here approximated as uniform);  $\tau_b$  is bed shear stress; and  $R$  is  
 242 submerged specific gravity of sediment, defined as  $(\rho_s - \rho) / \rho$ , in which  $\rho_s$  is density of sediment, and  $\rho$  is density of water.  
 243 The sediment submerged specific gravity  $R$  is specified as 1.65 in this paper, which is an appropriate estimate for natural rivers,  
 244 and corresponds to quartz.

245 In the relation of Ma et al. (2017), the dimensionless coefficient  $\alpha_s = 0.9$  and the dimensionless exponent  $n_s = 1.68$ .  
 246 These values are quite different from the original relation of Engelund and Hansen (1967), in which  $\alpha_s = 0.05$  and  $n_s = 2.5$ .  
 247 Ma et al. (2017) demonstrated that such differences imply that the riverbed of the LYR is dominated by low-amplitude bedform  
 248 features (dunes) approaching upper-regime plane bed. According to this finding, form drag is then neglected in our modeling,  
 249 and all of the bed shear stress is used for sediment transport.

## 250 **2.4.2 Sediment mixtures**

251 We implement the relation of Naito et al. (accepted subject to revision) to calculate the equilibrium sediment transport  
 252 rate of size mixtures. Using field data from the LYR, Naito et al. (accepted subject to revision) extended the Engelund and  
 253 Hansen (1967) relation to a surface-based grain-size specific form, in which the suspended load transport rate of the  $i$ -th size  
 254 range is tied to the availability of this size range on the bed surface:

$$255 \quad q_{sei} = \frac{N_i^* F_i u_*^3}{R g C_f} \quad (22)$$

256 where  $N_i^*$  is the dimensionless sediment transport rate in the  $i$ -th size range, and  $u_*$  is shear velocity calculated from the bed  
 257 shear stress  $\tau_b$ :

$$258 \quad u_* = \sqrt{\frac{\tau_b}{\rho}} \quad (23)$$

259 The transport relation itself takes the form,

$$260 \quad N_i^* = A_i \left( \tau_g^* \frac{D_{sg}}{D_i} \right)^{B_i} \quad (24)$$

261 in which  $D_i$  is the characteristic grain size for sediment in the  $i$ -th size range,  $D_{sg}$  is the geometric mean grain size in the active  
 262 layer, and  $\tau_g^*$  is the dimensionless bed shear stress associated with  $D_{sg}$ . The parameters  $\tau_g^*$ , coefficient  $A_i$ , and exponent  $B_i$  are  
 263 calculated as,

$$264 \quad \tau_g^* = \frac{\tau_b}{\rho R g D_{sg}} \quad (25)$$

$$265 \quad A_i = 0.46 \left( \frac{D_i}{D_{sg}} \right)^{-0.84} \quad (26)$$

$$266 \quad B_i = 0.35 \left( \frac{D_i}{D_{sg}} \right)^{-1.16} \quad (27)$$

267            If  $A_i$  and  $B_i$  are specified as constant values in Eq (24), then the sediment transport rate for each size range depends  
 268 only on the flow shear stress and the characteristic grain size of this size range, without being affected by other size ranges.  
 269 But according to Eqs. (26) and (27), the coarser the sediment the smaller the values of  $A_i$  and  $B_i$  will be, thus leading to reduced  
 270 mobility for coarse sediment (and increased mobility for fine sediment) due to the presence of grains of other sizes. Thus the  
 271 relations (26) and (27) serve as hiding function that allow for grain sorting.

272            We note that a form of the Engelund-Hansen equation for mixtures was introduced by Van der Scheer et al. (2002),  
 273 and implemented by Blom et al. (2016). Blom et al. (2017) further extended this relation to a more general framework which  
 274 is capable of including hiding effects. These forms, however, have not been calibrated to the LYR data and are thus not suitable  
 275 for the LYR.

### 276 **3. Numerical modeling of the LYR using the two forms of Exner equation**

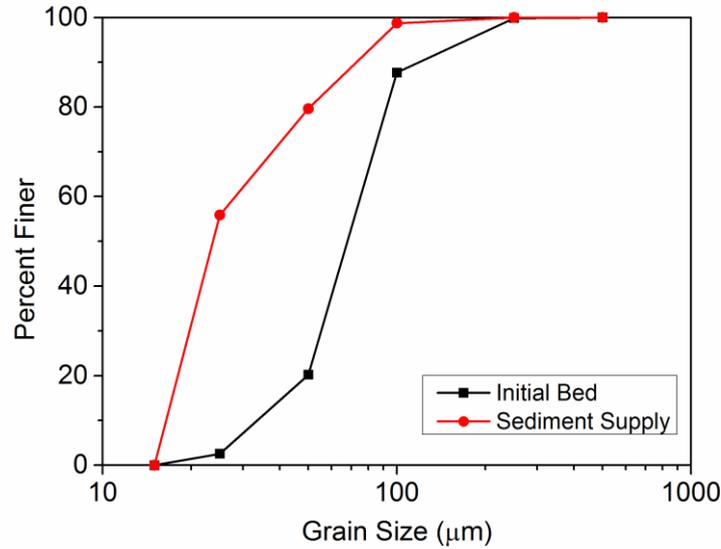

277            In this section, we conduct numerical simulations using both the flux form and the entrainment form of the Exner  
 278 equation, with the aim to study under what circumstances the two forms give different predictions. Numerical simulations are  
 279 conducted in the setting of the LYR. We specify a 200 km long channel reach for our simulations, along with a constant  
 280 channel width of 300 m and an initial longitudinal slope of 0.0001. Bed porosity  $\lambda_p$  is specified as 0.4. Based on field  
 281 measurements of the LYR available to us, we implemented a dimensionless Chezy resistance coefficient  $C_z$  of 30, which  
 282 corresponds to a dimensionless bed resistance coefficient  $C_f$  of 0.0011. For the entrainment form of Exner equation, we specify  
 283 the ratio of near bed sediment concentration to flux-averaged sediment concentration  $r_0$  ( $r_{0i}$ ) = 1. Such a value of  $r_0$  ( $r_{0i}$ )  
 284 corresponds to a vertically uniform profile of sediment concentration, and will thus give a maximum difference between the  
 285 prediction of entrainment form and the prediction of the flux form. More discussion about the effects of  $r_0$  is presented in  
 286 Section 4.3.

287            A constant flow discharge of 2000 m<sup>3</sup>/s (corresponding to a flow discharge per unit width  $q_w$  of 6.67 m<sup>2</sup>/s) is  
 288 introduced at the inlet of the channel with the flood intermittency factor  $I_f$  estimated as 0.14 (Naito et al., accepted subject to  
 289 revision). The downstream end is specified far from the river mouth to neglect the effects of backwater. Therefore, the bed

290 elevation is held constant and the water depth is specified as the normal flow depth at the downstream end of the calculational  
291 domain. The above flow discharge per unit width  $q_w$  combined with the bed slope  $S$  as well as the bed resistance coefficient  $C_f$   
292 leads to a normal flow depth of 3.69 m. In our simulation, we use the height of bedforms in the LYR to determine the thickness  
293 of the active layer (Blom, 2008). According to the field survey of Ma et al. (2017), the characteristic height of bedforms in the  
294 LYR is about 20% of the normal flow depth, which can fall in the range suggested by the data analysis of Bradley and Venditti  
295 (2017). This eventually leads to an estimate of active layer thickness of  $L_a = 0.738$  m. The sublayer in the substrate to store the  
296 vertical stratigraphy is specified with a thickness of 0.5 m.

297 Two cases are considered here. In the first case, the sediment grain size distribution of LYR is simplified to a uniform  
298 grain size of 65  $\mu\text{m}$ . This is based on the measured grain size distribution of bed material at the Lijin gauging station, which  
299 has a median grain size of  $D_{50} = 66.6$   $\mu\text{m}$ , a geometric mean grain size of  $D_g = 65.5$   $\mu\text{m}$ , and a geometric standard deviation  
300  $\sigma_g = 2.0$ , as shown in Fig. 1(c). In the second case, we consider the effects of sediment mixtures. The grain size distribution of  
301 the initial bed is based on the bed material at the Lijin gauging station, as shown in Fig. 1(c), but we renormalize the measured  
302 grain size distribution with a cutoff for washload at 15  $\mu\text{m}$  as suggested by Ma et al. (2017). The renormalized grain size  
303 distribution for the initial bed as implemented in the case of sediment mixtures is shown in Fig. 2, with a total number of grain  
304 size fractions of 5. In both the two cases, simulations start with an equilibrium state where sediment supply rate, sediment  
305 transport rate, and equilibrium sediment transport rate being the same, so that the initial state of the channel is in equilibrium.  
306 Then we cut the sediment supply rate (of each size range) to only 10% of the equilibrium sediment transport rate and keep this  
307 sediment supply rate. This is to mimic the reduction of sediment load in the LYR in recent years, as shown in Fig. 1(b). The  
308 grain size distribution of sediment supply in the case of sediment mixtures is shown in Fig. 2.

309 The 200 km channel reach is discretized into 401 cells, with cell size  $\Delta x$  of 500 m. In the case of uniform sediment,  
310 we specify a time step for morphologic calculation  $\Delta t_m = 10^{-4}$  year and a time step for hydraulic calculation  $\Delta t_h = 10^{-6}$  year. In  
311 the case of sediment mixtures, we specify a time step for morphologic calculation  $\Delta t_m = 10^{-5}$  year, and a time step for hydraulic  
312 calculation  $\Delta t_h = 10^{-6}$  year. Computational conditions are briefly summarized in Table 1. The computational conditions we  
313 implement are much simpler than the rather complicated conditions of the actual LYR. But it should be noted that the aim of  
314 this paper is not to reproduce specific aspects of the morphodynamic processes of LYR, but to compare the flux form and  
315 entrainment form of Exner equation in the context of conditions typical of LYR.

316  
317 **Figure 2.** Grain size distributions of both the initial bed and the sediment supply in the case of sediment mixtures. For the  
318 initial bed, the surface and substrate grain size distributions are the same. The grain size distribution of the initial bed is  
319 renormalized based on the field data at the Lijin gauging station. The grain size distribution of the sediment supply equals to  
320 the grain size distribution of bed material load at equilibrium. Grain sizes in the range of washload have been removed from  
321 both distributions.

322 **Table 1.** Summary of computational conditions for numerical modeling of the LYR.

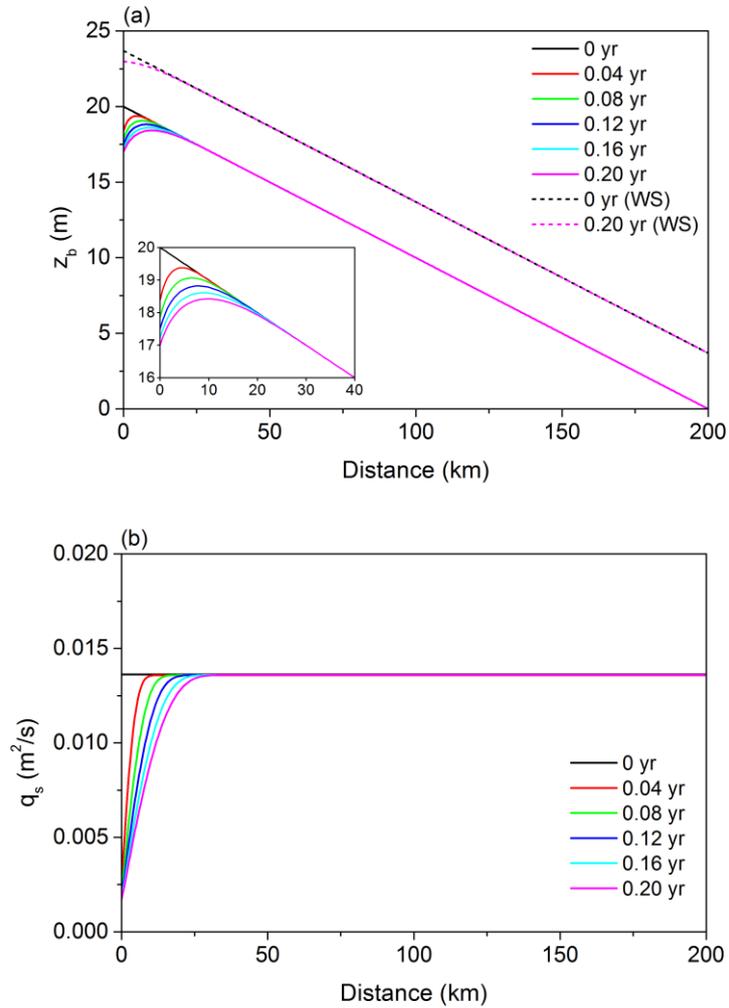

Parameter	Value
Channel length $L$	200 km
Channel width $B$	300 m
Initial slope $S_f$	0.0001
Dimensionless Chezy resistance coefficient $C_z$	30
Flow discharge per unit width $q_w$	6.67 m <sup>2</sup> /s
Flood intermittency factor $I_f$	0.14
ratio of near bed concentration to average concentration $r_0$ ( $r_{0i}$ )	1
Characteristic grain size in the case of uniform sediment	65 μm
Submerged specific gravity of sediment $R$	1.65
Porosity of bed deposits $\lambda_p$	0.4
cell size $\Delta x$	500 m
time step for morphologic calculation $\Delta t_m$	10 <sup>-4</sup> year (uniform sediment) 10 <sup>-5</sup> year (sediment mixtures)
time step for hydraulic calculation $\Delta t_h$	10 <sup>-6</sup> year

323

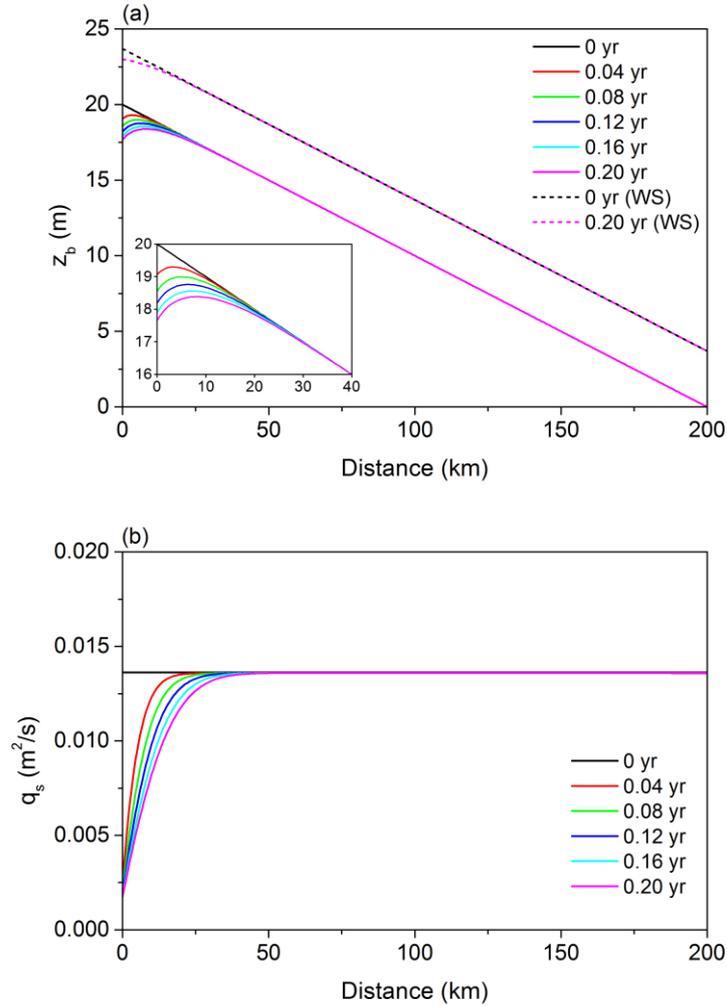

### 324 3.1 Case of uniform sediment

325 In this case, we implement a uniform grain size of 65  $\mu\text{m}$  for both the bed material and sediment supply. Such a grain  
326 size is nearly equal to the observed median grain size (or geometric mean grain size) of bed material at Lijin gauging station.  
327 The relation of Ma et al. (2017) is implemented to calculate the transport rate of bed material suspended load. This relation  
328 provides an equilibrium sediment transport rate per unit width  $q_{se}$  of 0.0136  $\text{m}^2/\text{s}$  under the given flow discharge, bed slope  
329 and sediment grain size. With a flood intermittency factor  $I_f$  of 0.14, this further gives a mean annual bed material load of 47.8  
330  $\text{Mt/a}$ . Adding in washload according to the estimate of Naito et al. (accepted subject to revision), total mean annual load is  
331 86.9  $\text{Mt/a}$ , a value that is of the same order of magnitude as averages over the period 2000-2016 (89-126  $\text{Mt/a}$  depending on  
332 site), i.e. since the operation of Xiaolangdi Dam in 1999 (Fig. 1(b)). The sediment supply rate  $q_{sf}$  we specify at the upstream  
333 end of the channel is only 10% of the equilibrium sediment transport rate (i.e. sediment supply rate is cut by 90% from the  
334 equilibrium state), such that  $q_{sf} = 0.00136 \text{ m}^2/\text{s}$ .

335 Figure 3 shows the modeling results using the flux form of the Exner equation. As we can see in the figure, the bed  
336 degrades and the sediment load decreases in response to the cutoff of sediment supply. Such adjustments start from the  
337 upstream end of the channel and gradually migrate downstream. Figure 4 shows the modeling results using the entrainment  
338 form of Exner equation. A comparison between Fig. 4 and Fig. 3 shows that the entrainment form and the flux form give very  
339 similar predictions in this case. The entrainment form provides a somewhat slower degradation (at the upstream end the flux  
340 form predicts a 3-m degradation whereas the entrainment form predicts a 2.3-m degradation) and a more diffusive sediment  
341 load reduction. Such more diffusive predictions of sediment load variation can be ascribed to the condition of nonequilibrium  
342 transport that is embedded in the entrainment form. This issue will be studied analytically in Section 4. Here we present the  
343 results for only 0.2 year after the cutoff of sediment supply, since the differences between the predictions of the two forms  
344 tend to be the most evident shortly after the disruption but gradually diminish as the river approaches the new equilibrium (El  
345 kadi Abderrezzak and Paquier, 2009). Modeling results over a longer time scale will be discussed in Section 4.3.

346  
 347 **Figure 3.** 0.2 year results for the case of uniform sediment using the flux form of Exner equation: time variation of (a) bed  
 348 elevation  $z_b$  and water surface (WS), (b) sediment load per unit width  $q_s$  of the LYR in response to the cutoff of sediment  
 349 supply. The inset shows detailed results near the upstream end.

350 **Figure 4.** 0.2 year results for the case of uniform sediment using the entrainment form of Exner equation: time variation of (a)  
 351 bed elevation  $z_b$  and water surface (WS), (b) sediment load per unit width  $q_s$  of the LYR in response to the cutoff of sediment  
 352 supply. The inset shows detailed results near the upstream end.  
 353

354 To further quantify the differences between the predictions of the two forms, we propose the following normalized  
 355 parameter,

$$356 \quad \delta(y) = \left| \frac{y_E - y_F}{y_F} \right| \times 100\% \quad (28)$$

357 where  $y$  denotes an arbitrary variable calculated by the morphodynamic model, and subscripts  $F$  and  $E$  denote results using the  
 358 flux form and the entrainment form respectively. Therefore,  $\delta(y)$  denotes the difference between the prediction the two forms  
 359  $y_F$  and  $y_E$  normalized by the prediction of the flux form  $y_F$ .

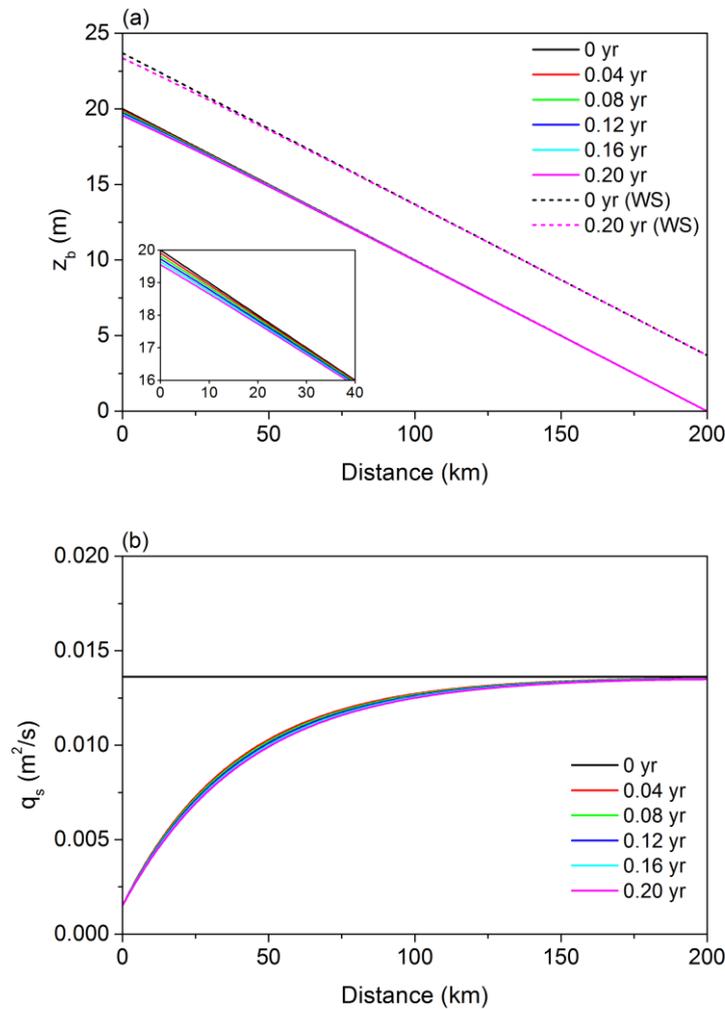

360 Table 2 gives a summary of the maximum values of  $\delta$  along the channel at different times in the case of uniform  
 361 sediment. The values of  $\delta$  for both  $z_b$  and  $q_s$  are presented. As we can see from the table, the maximum value of  $\delta(z_b)$  along the  
 362 calculational domain stays within 4% in the first 0.2 year after the cutoff of sediment supply. This indicates that the flux form  
 363 and the entrainment form can indeed give almost the same prediction in terms of bed elevation in this case. But in the case of  
 364 the sediment load per unit width  $q_s$ , the maximum value of  $\delta(q_s)$  can be as high as 20%, indicating that even though the two  
 365 forms give qualitatively similar patterns of evolution in terms of sediment load as shown in Figs. 3 and 4, a quantitative  
 366 difference is clearly evident due to the more diffusive nature of the predictions of the entrainment form. The value of  $\delta(q_s)$  is  
 367 largest at the beginning of the simulation, and then gradually reduces with time. It should be noted that the values of  $\delta(z_b)$   
 368 depend on the choice of elevation datum. In this paper bed elevation at the downstream end is fixed as 0 m, which serves as  
 369 the elevation datum. In the simulation of this paper, the maximum value of  $\delta(z_b)$  almost always occurs at the upstream end,  
 370 where bed elevation deviates not too far from the initial value of 20 m.

371 **Table 2.** Quantification of the difference between predictions of the flux form and the entrainment form in the case of uniform  
 372 sediment. The maximum values of  $\delta(z_b)$  and  $\delta(q_s)$  in the calculational domain are presented every 0.04 year.

		0.04 yr	0.08 yr	0.12 yr	0.16 yr	0.20 yr
original $v_s$	$\delta(z_b)$	3.7 %	3.9 %	3.9 %	3.9 %	3.8 %
	$\delta(q_s)$	20.5 %	15.1 %	12.3 %	10.5 %	9.2 %
$v_s$ multiplied by 0.05	$\delta(z_b)$	8.2 %	10.9 %	12.7 %	13.9 %	14.9 %
	$\delta(q_s)$	74.8 %	68.1 %	63.0 %	58.9 %	55.4 %

373  
 374 The above results show that the flux form and the entrainment form can provide similar predictions of LYR when the  
 375 bed sediment grain size distribution is simplified to a uniform value of 65  $\mu\text{m}$ . To understand under what conditions the two  
 376 forms will lead to more different results, we conduct an idealized run using the entrainment form in which the sediment fall  
 377 velocity  $v_s$  is arbitrarily multiplied by a factor of 0.05. That is to say, we keep the sediment grain size at 65  $\mu\text{m}$  in the  
 378 computation of the Shields number, but let the sediment fall velocity in Eqs. (8) and (10) equal only 1/20 of the value calculated  
 379 by the relation of Dietrich (1982) from this grain size. With a much smaller, and indeed intentionally unrealistic sediment fall  
 380 velocity, the entrainment form predicts very different results as shown in Fig. 5. The adjustment of the sediment load become  
 381 even more diffusive in space: it takes almost the entire 200 km reach for the sediment load to adjust from the upstream  
 382 disruption to the equilibrium transport rate. Meanwhile, there is barely any bed degradation at the upstream end after 0.2 year,  
 383 in correspondence with the fact that the spatial gradient of  $q_s$  becomes quite small. In Table 2 we also exhibit the  $\delta$  values for

384 this idealized run. It is no surprise that both  $\delta(z_b)$  and  $\delta(q_s)$  are high, as the entrainment form and flux form predict very different  
385 patterns with such an arbitrarily reduced sediment fall velocity.

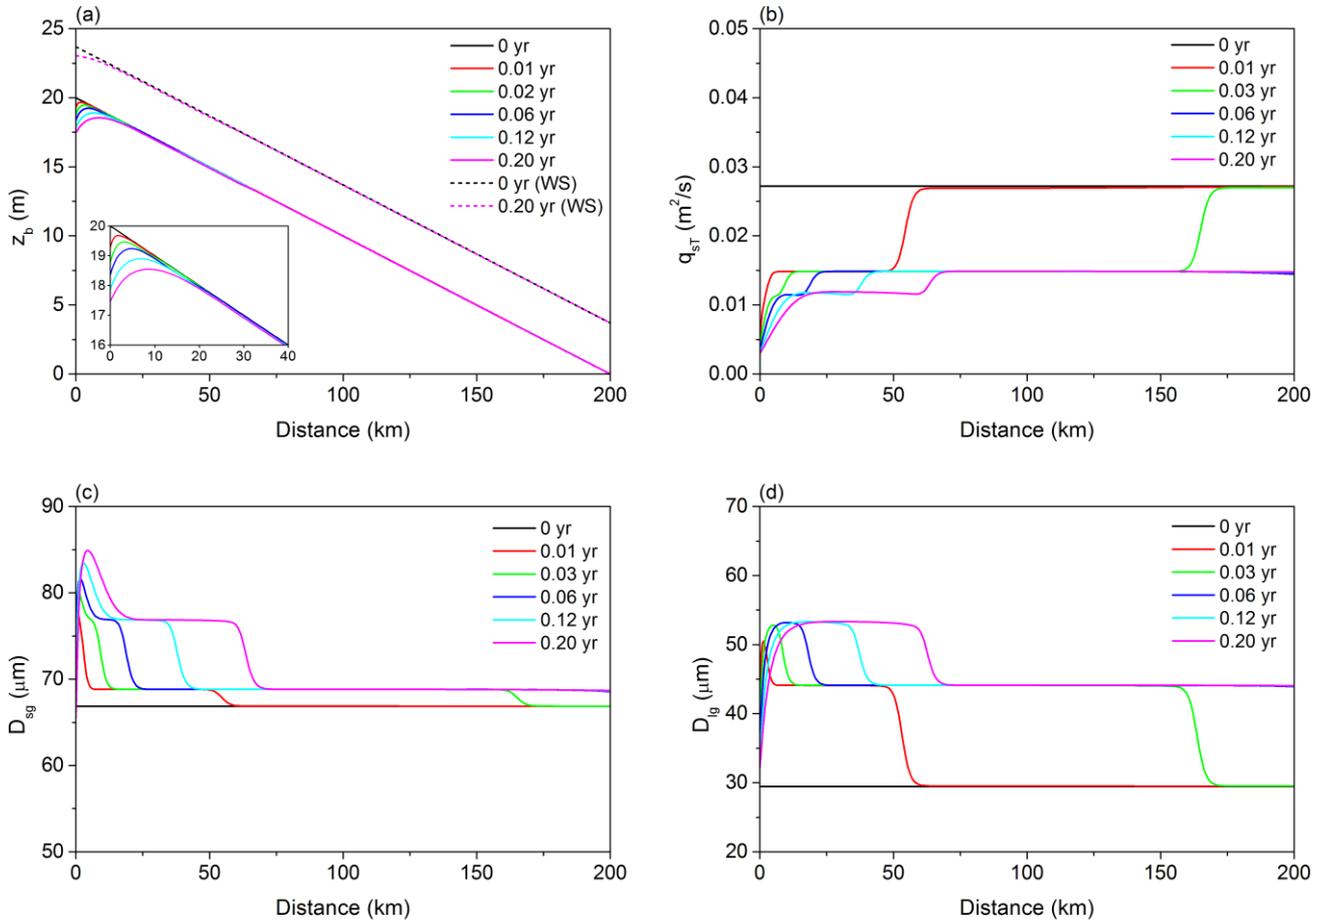

386  
387 **Figure 5.** 0.2 year results for the case of uniform sediment using the entrainment form of Exner equation: time variation of (a)  
388 bed elevation  $z_b$  and water surface (WS), (b) sediment load per unit width  $q_s$  of the LYR in response to the cutoff of sediment  
389 supply. Sediment fall velocity  $v_s$  is arbitrarily multiplied by a factor of 0.05 while holding bed grain size constant in this run.  
390 The inset shows detailed results near the upstream end.

391 In Section S2 of the Supplement, we also conduct numerical simulations with hydrographs. Results indicate that our  
392 conclusions based on constant flow discharge also hold when hydrographs are considered: the flux-form and the entrainment  
393 form (with the sediment fall velocity not adjusted) of the Exner equation give very similar prediction using a characteristic  
394 grain size of 65  $\mu m$ .

396 In this section we consider the morphodynamics of sediment mixtures rather than the case of a uniform bed grain size  
397 implemented in section 3.1. The grain size distribution of the initial bed is based on field data at the Lijin gauging station, and  
398 is shown in Fig. 2. Using the sediment transport relation of Naito et al. (accepted subject to revision) for mixtures, such a grain  
399 size distribution combined with the given bed slope and flow discharge leads to a total equilibrium sediment transport rate per  
400 unit width  $q_{seT}$  of  $0.0272 \text{ m}^2/\text{s}$ . With a flood intermittency factor  $I_f$  of 0.14, this further gives a mean annual bed material load  
401 of 95.5 Mt/a. Adding in washload according to the estimate of Naito et al. (accepted subject to revision), total mean annual  
402 load 173.7 Mt/a, a value that is of the same order of magnitude as averages over the period 2000-2016 (89-126 Mt/a depending  
403 on site), i.e. since the operation of Xiaolangdi Dam in 1999 (Fig. 1(b)). The sediment supply rate of each grain size range is  
404 set at 10% of its equilibrium sediment transport rate. This results in a total sediment supply rate of  $q_{sf} = 0.00272 \text{ m}^2/\text{s}$ , and a  
405 grain size distribution of the sediment supply (shown in Fig. 2) that is identical to the grain size distribution of the equilibrium  
406 sediment load before the cutoff. That is, the grain size distribution of sediment supply does not change, only the total sediment  
407 supply is reduced by 90%. Again we exhibit simulation results for only 0.2 year here, a value that is enough to show the  
408 differences between the two forms, flux and entrainment, as applied to mixtures. Modeling results over a longer time scale are  
409 presented in Section 4.3.

410 Figure 6 shows the simulation results using the flux form of the Exner equation. As a result of the reduced sediment  
411 supply at the inlet, bed degradation occurs first at the upstream end and then gradually migrates downstream. The total sediment  
412 transport rate per unit width  $q_{sT}$  also reduces as a response to the cutoff of sediment supply. More specifically, the evolution  
413 of  $q_{sT}$  shows marked evidence of advection, with at least two kinematic waves being observed within 0.2 year. Actually as  
414 illustrated by Stecca et al. (2014, 2016), each grain size fraction should induce a migrating wave. As shown in Fig. 6(b), the  
415 fastest kinematic wave migrates beyond the 200 km reach within 0.06 year, and the second fastest kinematic wave migrates  
416 for a distance of about 60 km in 0.2 year. Figures 6(c) and 6(d) show the results for the surface geometric mean grain size  $D_{sg}$   
417 and geometric mean grain size of suspended load  $D_{lg}$  respectively. As can be seen therein, both the bed surface and the  
418 suspended load coarsen as a result of the cutoff of sediment supply This represents armoring, mediated by the hiding functions  
419 of Eqs. (26) and (27). Such coarsening is not evident near the upstream end, possibly due to the inverse slope visible in Fig.  
420 6(a). Similarly to the variation of  $q_{sT}$ , the patterns of time variation of both  $D_{sg}$  and  $D_{lg}$  also exhibit very clear kinematic waves,  
421 with migration rates about the same as those of  $q_{sT}$ .

422

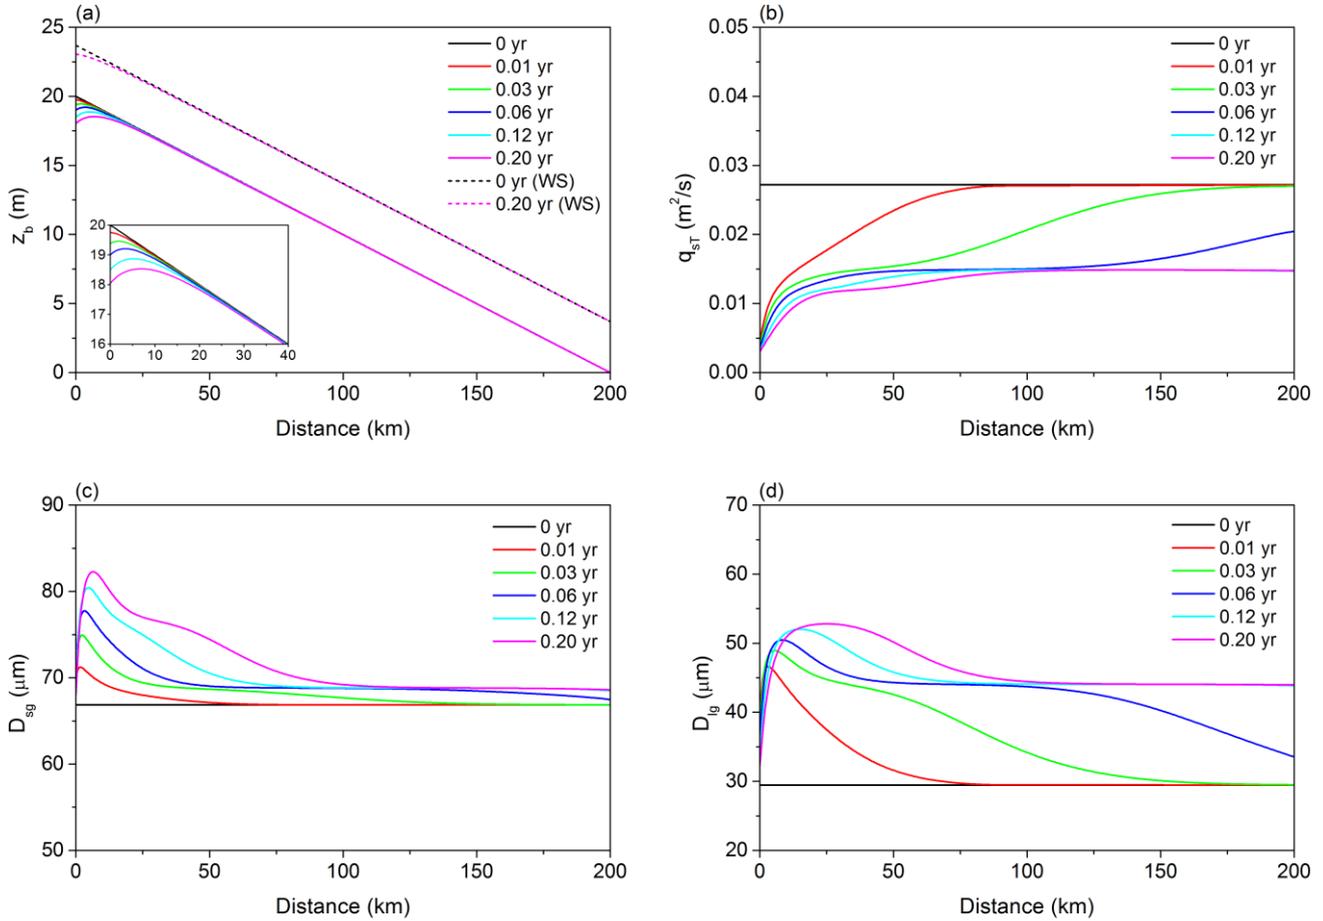

423 **Figure 6.** 0.2 year results for the case of sediment mixtures using the flux form of Exner equation: time variation of (a) bed  
 424 elevation  $z_b$  and water surface (WS), (b) total sediment load  $q_{sT}$ , (c) surface geometric mean grain size  $D_{sg}$  and (d) geometric  
 425 mean grain size of sediment load of the LYR in response to the cutoff of sediment supply. The inset shows detailed results  
 426 near the upstream end.  
 427

428 Figure 7 shows the simulation results obtained using the entrainment form of the Exner equation. In general, the  
 429 patterns of variation predicted by the entrainment form have similar trends and magnitudes to those predicted by the flux form:  
 430 the bed degrades near the upstream end, the suspended load transport rate reduces in time, and both the bed surface and the  
 431 suspended load coarsen as a result of the cutoff of sediment supply. But the results based on the two forms exhibit very evident  
 432 differences when multiple grain sizes are included. That is, the results predicted by the entrainment form are sufficiently  
 433 diffusive so that the variations of  $q_{sT}$ ,  $D_{sg}$ , and  $D_{lg}$  (Figs. 7(b), 7(c) and 7(d)) do not show the advective character seen in Fig.  
 434 6. Figure 7c, however, shows the same armoring as in the case of calculations with the flux form. No clear kinematic waves  
 435 can be observed in Fig. 7. Table 3 gives a summary of the values of  $\delta$  in the case of sediment mixtures. The prediction of bed

436 elevation is not affected much when multiple grain sizes are considered, with  $\delta(z_b)$  being no more than 3.5% within 0.2 year.  
 437 The  $\delta$  values of  $q_{sT}$ ,  $D_{sg}$ , and  $D_{lg}$  are, however, relatively large since the two forms predict quite different patterns of variations,  
 438 as shown in Fig. 6 and Fig. 7.

439

440

441 **Figure 7.** 0.2 year results for the case of sediment mixtures using the entrainment form of Exner equation: time variation of  
 442 (a) bed elevation  $z_b$  and water surface (WS), (b) total sediment load  $q_{sT}$ , (c) surface geometric mean grain size  $D_{sg}$  and (d)  
 443 geometric mean grain size of sediment load of the LYR in response to the cutoff of sediment supply. The inset shows detailed  
 444 results near the upstream end.

The results shown in Fig. 8 have also been calculated using the entrainment form of the Exner equation, but here the sediment fall velocities  $v_{si}$  used in Eqs. (14)-(16) are arbitrarily multiplied by a factor of 20. That is, we still apply the grain size distribution in Fig. 2, but the sediment fall velocities implemented in the simulation are 20 times the corresponding fall velocities calculated by the relation of Dietrich (1982). In the case of uniform sediment in Section 3.1, we arbitrarily reduce the sediment fall velocity to force a difference between the predictions from the entrainment form and those from the flux form. Here we arbitrarily increase the sediment fall velocity with the aim of determining under what conditions the sorting patterns predicted by the two forms converge. As we can see in Fig. 8, with such a larger and intentionally unrealistic sediment fall velocity, the general trend of variations predicted by the entrainment form does not change, but the results show a notably less diffusive pattern. The variations of  $q_{sT}$ ,  $D_{sg}$ , and  $D_{lg}$  show more advection compared with Fig. 7, and at least two kinematic waves appear within 0.2 year. It should be noted that even though these kinematic waves appear after we arbitrarily increase the sediment fall velocity, they are more diffusive than those obtained from the flux formulation and also migrate with a slower celerity as compared with those predicted by the flux form, especially for the fastest kinematic wave in the modeling results.

Table 3 summarizes the  $\delta$  values for this run. The values of  $\delta(z_b)$  become smaller with arbitrarily increased sediment fall velocities except for  $t = 0.06$  year. A relatively large value of  $\delta(z_b)$  at  $t = 0.06$  year occurs near the downstream end of the channel, where the entrainment form predicts some slight degradation. Also,  $\delta(q_{sT})$  is quite large at  $t = 0.01$  year and 0.03 year, even though the results for the case of increased fall velocities become qualitatively more similar to the prediction of the flux form. This is because the flux form and the entrainment form with arbitrarily increased sediment fall velocities predict different celerities for the fastest kinematic wave. The error  $\delta(q_{sT})$  becomes smaller from  $t = 0.06$  year as the fastest kinematic wave migrates beyond the channel reach. The error  $\delta(D_{lg})$  behaves similarly to  $\delta(q_{sT})$ , with  $\delta(D_{lg})$  being quite large at  $t = 0.01$  year and 0.03 year near the fastest kinematic wave, but gradually becoming smaller as time passes. The error  $\delta(D_{sg})$  stays low within the whole 0.2-year period, possibly because the fastest kinematic wave of  $D_{sg}$  has a small magnitude, as shown in Fig. 8(c).

470  
 471 **Figure 8.** 0.2 year results for the case of sediment mixtures using the entrainment form of Exner equation: time variation of  
 472 (a) bed elevation  $z_b$  and water surface (WS), (b) total sediment load  $q_{sT}$ , (c) surface geometric mean grain size  $D_{sg}$  and (d)  
 473 geometric mean grain size of sediment load of the LYR in response to the cutoff of sediment supply. Sediment fall velocities  
 474  $v_{si}$  are arbitrarily multiplied by a factor of 20 in this run while keeping the grain sizes invariant. The inset shows detailed results  
 475 near the upstream end.

476 In Section S3 of the Supplement, we conduct additional numerical cases which are similar to the cases in this section,  
 477 except that hydrographs are implemented instead of constant discharge. Results indicate that our conclusions based on constant  
 478 flow discharge also hold when hydrographs are considered. The flux form and the entrainment form (with the sediment fall  
 479 velocity not adjusted) of the Exner equation predict quite different patterns of grain sorting, with the flux form exhibiting more  
 480 advective character than the entrainment form.

481 **4. Discussion**

482 **4.1 Adjustment of sediment load and the adaptation length**

483 In Section 3.1, our simulation shows that in the case of uniform sediment, the flux form and the entrainment form of  
484 the Exner equation give very similar predictions for a given sediment size of 65  $\mu\text{m}$ . However, if we arbitrarily reduce the  
485 sediment fall velocity by a multiplicative factor of 0.05, the prediction given by the entrainment form will become much more  
486 diffusive, in terms of both  $z_b$  and  $q_s$ . The diffusive nature of the entrainment form as well as the important role played by the  
487 sediment fall velocity can be explained in terms of the governing equation.

488 In the entrainment form, the equation governing suspended sediment concentration is,

489 
$$\frac{1}{I_f} \frac{\partial(hC)}{\partial t} + \frac{\partial(huC)}{\partial x} = v_s (E - r_0 C) \quad (29)$$

490 i.e. the same as Eq. (11). The sediment transport rate per unit width  $q_s = huC = q_w C$ , and the dimensionless entrainment rate  
491  $E = r_0 q_{se} / q_w$ . In order to simplify the mathematical analysis, here we consider only the adjustment of sediment concentration in  
492 space and neglect the temporal derivative in Eq. (29), so that we get

493 
$$\frac{\partial q_s}{\partial x} = v_s (E - r_0 C) = \frac{1}{L_{ad}} (q_{se} - q_s) \quad (30)$$

494 
$$L_{ad} = \frac{q_w}{v_s r_0} \quad (31)$$

495 where  $L_{ad}$  can be identified as the adaptation length for suspended sediment to reach equilibrium. This definition of adaptation  
496 length is similar to those in Wu and Wang (2008), and Ganti et al. (2014).

497 If we consider the spatial adjustment of sediment load shortly after the cutoff of sediment supply, we can further  
498 neglect the nonuniformity of the capacity (equilibrium) transport rate  $q_{se}$  along the channel, and Eq. (30) can be solved with a  
499 given upstream boundary condition. That is, with the boundary condition

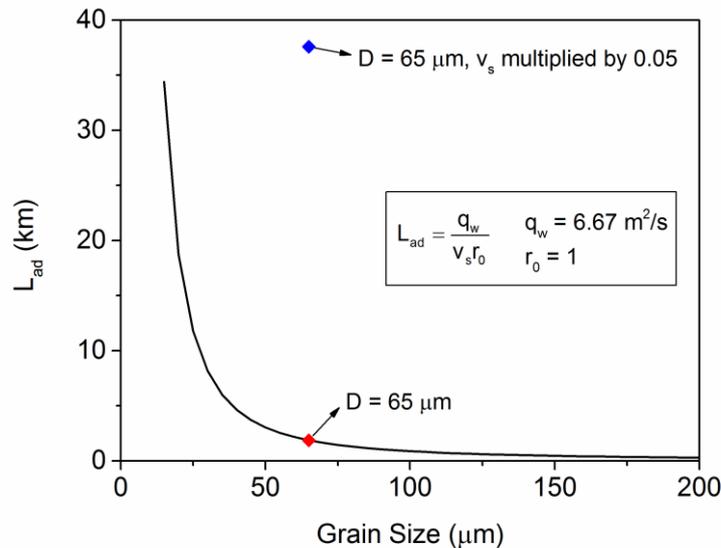

500 
$$q_s \Big|_{x=0} = q_{sf} \quad (32)$$

501 Eq. (30) can be solved to yield

502 
$$q_s = q_{se} + (q_{sf} - q_{se}) e^{-\frac{x}{L_{ad}}} \quad (33)$$

503 Here  $q_{sf}$  is the sediment supply rate per unit width at the upstream end. According to Eq. (33),  $q_s$  adjusts exponentially in space  
 504 from  $q_{sf}$  to  $q_{se}$ , which also coincides with our simulation results in Section 3.1, as shown in Figs. 3-6. The adaptation length  
 505  $L_{ad}$  is the key parameter that controls the distance for  $q_s$  to approach the equilibrium sediment transport rate  $q_{se}$ . More  
 506 specifically,  $q_s$  attains  $1 - 1/e$  (i.e. 63.2%) of its adjustment from  $q_{sf}$  to  $q_{se}$  over a distance  $L_{ad}$ . Therefore, the larger the adaptation  
 507 length, the slower  $q_s$  adjusts in space, so that the more evident lag effects and diffusivity are exhibited in the entrainment form.  
 508 In the flux form, however, the sediment load responds simultaneously with the flow conditions, so that  $L_{ad} = 0$  and  $q_s = q_{se}$   
 509 along the entire channel reach.

510 For the case of uniform sediment in Section 3.1,  $q_w = 6.67 \text{ m}^2/\text{s}$  and  $r_0$  is specified as unity. Therefore, the value of  
 511  $L_{ad}$  is determined only by the sediment fall velocity  $v_s$ . Figure 9 shows the value of the adaptation length  $L_{ad}$  for various  
 512 sediment grain sizes, with the sediment fall velocity  $v_s$  calculated by the relation of Dietrich (1982). From the figure we can  
 513 see that  $L_{ad}$  decreases sharply with the increase of grain size, indicating that the lag effects between sediment transport and  
 514 flow conditions are evident for very fine sediment but gradually disappear when sediment is sufficiently coarse. For the  
 515 sediment grain size of  $65 \text{ }\mu\text{m}$  implemented in Section 3.1, the corresponding  $L_{ad} = 1.88 \text{ km}$ , which is much smaller than the  
 516  $200 \text{ km}$  reach of the computational domain. In this case and in general, the predictions of the flux form and the entrainment  
 517 form show little difference when  $L_{ad}/L \ll 1$ , where  $L$  is domain length. However, if we arbitrarily multiply the sediment fall  
 518 velocity by a factor of 0.05, then  $L_{ad}$  becomes  $37.60 \text{ km}$ . With such a large adaptation length, it is no surprise that the  
 519 entrainment form gives very different predictions from the flux form.

520 **Figure 9.** Relation between adaptation length  $L_{ad}$  and grain size  $D$ . The values of flow discharge per unit width  $q_w$  and recovery  
 521 coefficient  $r_0$  are the same as those in Section 3.1. The relation of Dietrich (1982) is implemented for sediment fall velocity.  
 522

523 The evolution of bed elevation  $z_b$  can also be affected by the value of  $L_{ad}$ . For example in the case of uniform sediment  
 524 in Section 3.1, the flux form corresponds to an adaption length of zero. As a result, the flux form yields a spatial derivative of  
 525  $q_s$  near the upstream end that is relatively large, thus leading to fast degradation from the upstream end. In the case of the  
 526 entrainment form, however, the spatial derivative of  $q_s$  is small with a large  $L_{ad}$ , thus leading to a slower and more diffusive  
 527 bed degradation. This is especially evident when we arbitrarily reduce the sediment fall velocity by a factor of 0.05, while  
 528 keeping grain size invariant.

529 The above analysis also holds for sediment mixtures, except that each grain size range will have its own adaptation  
 530 length. Here we neglect the temporal derivative in Eq. (29) and analyze only the spatial adjustment of sediment load. If we  
 531 neglect the spatial derivative in Eq. (29) and conduct a similar analysis for sediment concentration, we would find that the  
 532 temporal adjustment of sediment concentration is also described by an exponential function of time, in analogy to Eq. (33).

#### 533 4.2 Patterns of grain sorting: advection vs. diffusion

534 In Section 3.2 we find that the flux form and entrainment form of the Exner equation provide very different patterns  
 535 of grain sorting for sediment mixtures: kinematic sorting waves are evident in the flux form but are diffused out in the  
 536 entrainment form. The diffusivity of grain sorting becomes smaller and the kinematic waves appear, however, if we arbitrarily  
 537 increase the sediment fall velocity by a factor of 20. In this section, we explain this behavior by analyzing the governing  
 538 equations.

539 First we rewrite the sediment transport relation of Naito et al. (accepted subject to revision) in the following form,

$$540 \quad q_{sei} = F_i q_{ri} \quad (34)$$

$$541 \quad q_{ri} = \frac{u_*^3}{RgC_f} A_i \left( \tau_g^* \frac{D_g}{D_i} \right)^{B_i} \quad (35)$$

542 Substituting Eq. (34) into Eq. (6), which is the governing equation for surface fraction  $F_i$  in the flux form, we get

$$543 \quad \frac{1}{I_f} (1 - \lambda_p) \left[ L_a \frac{\partial F_i}{\partial t} + (F_i - f_{li}) \frac{\partial L_a}{\partial t} \right] = f_{li} \frac{\partial \sum_{j=1}^n F_j q_{rj}}{\partial x} - \frac{\partial F_i q_{ri}}{\partial x} \quad (36)$$

544 Equation (36) can be written in the form of a kinematic wave equation with source terms as below,

$$545 \quad \frac{\partial F_i}{\partial t} + c_{Fi} \frac{\partial F_i}{\partial x} = SF_i \quad (37)$$

$$546 \quad c_{Fi} = \frac{I_f q_{ri}}{(1-\lambda_p)L_a} (1-f_{li}) \quad (38)$$

$$547 \quad SF_i = -\frac{I_f F_i (1-f_{li})}{(1-\lambda_p)L_a} \frac{\partial q_{ri}}{\partial x} + \frac{I_f f_{li}}{(1-\lambda_p)L_a} \frac{\partial \sum_{j=1}^{n, j \neq i} F_j q_{rj}}{\partial x} - \frac{F_i - f_{li}}{1-\lambda_p} \frac{\partial L_a}{\partial t} \quad (39)$$

548 where  $c_{Fi}$  is the  $i$ -th celerity of kinematic wave and  $SF_i$  denotes source terms. Since the surface geometric mean grain size  $D_{sg}$ ,  
549 the total sediment load per unit width  $q_{sT}$  (which equals the equilibrium sediment transport rate  $q_{seT}$ ), and the geometric mean  
550 grain size of sediment load  $D_{lg}$  are all closely related to the surface grain size fractions  $F_i$ , the evolution of these three  
551 parameters shows marked advective behavior when simulated by the flux form of the Exner equation. However, the evolution  
552 of bed elevation  $z_b$  is related to  $\partial q_{sT}/\partial x$ , which is dominated by diffusion if  $q_{sT}$  is predominantly slope-dependent (as is the  
553 case here). The advection-diffusion character of the flux form of Exner equation for sediment mixtures has been documented  
554 thoroughly in a series of papers (e.g. Stecca et al., 2014; Stecca et al., 2016; An et al., 2017). The reader can reference these  
555 papers for more details.

556 Now we turn to the entrainment form of the Exner equation. Combined with the sediment transport rate per unit width  
557  $q_{si} = huC_i = q_w C_i$  and the dimensionless entrainment rate  $E_{i-} = r_{0i} q_{sei}/q_w$ , Eq. (16) and Eq. (15) can be written as,

$$558 \quad \frac{1}{I_f} \frac{\partial \left( \frac{q_{si}}{u} \right)}{\partial t} + \frac{\partial q_{si}}{\partial x} = \frac{v_{si} r_{0i}}{q_w} (q_{sei} - q_{si}) \quad (40)$$

$$559 \quad \frac{1}{I_f} (1-\lambda_p) \left[ L_a \frac{\partial F_i}{\partial t} + (F_i - f_{li}) \frac{\partial L_a}{\partial t} \right] = f_{li} \sum_{j=1}^n \frac{v_{sj} r_{0j}}{q_w} (q_{sej} - q_{sj}) - \frac{v_{si} r_{0i}}{q_w} (q_{sei} - q_{si}) \quad (41)$$

560 where Eq. (40) denotes the conservation of suspended sediment and Eq. (41) denotes the conservation of bed material. If we  
561 rewrite Eq. (40) in the following form,

$$562 \quad q_{si} = q_{sei} - \frac{q_w}{v_{si} r_{0i}} \left[ \frac{1}{I_f} \frac{\partial \left( \frac{q_{si}}{u} \right)}{\partial t} + \frac{\partial q_{si}}{\partial x} \right] \quad (42)$$

563 then  $q_{si}$  can be solved iteratively. With an initial guess of  $q_{si} = q_{sei}$  and neglecting the temporal derivatives, we obtain the second  
564 order solution of  $q_{si}$  as,

$$q_{si} = q_{sei} - \frac{q_w}{v_{si}r_{oi}} \frac{\partial}{\partial x} \left( q_{sei} - \frac{q_w}{v_{si}r_{oi}} \frac{\partial q_{sei}}{\partial x} \right) \quad (43)$$

566 Details of the iteration scheme are given in Section S4 of the Supplement.

567 Substituting Eq. (43) and Eq. (34) into Eq. (41), we find that

$$\frac{1}{I_f} (1 - \lambda_p) \left[ L_a \frac{\partial F_i}{\partial t} + (F_i - f_{li}) \frac{\partial L_a}{\partial t} \right] = f_{li} \sum_{j=1}^n \frac{\partial}{\partial x} \left( F_j q_{rj} - \frac{q_w}{v_{sj}r_{oj}} \frac{\partial F_j q_{rj}}{\partial x} \right) - \frac{\partial}{\partial x} \left( F_i q_{ri} - \frac{q_w}{v_{si}r_{oi}} \frac{\partial F_i q_{ri}}{\partial x} \right) \quad (44)$$

569 Expanding out the last two terms in Eq. (44) using the chain rule, after some work the relation for the conservation of bed  
570 material can be expressed as,

$$\frac{\partial F_i}{\partial t} + c_{Ei} \frac{\partial F_i}{\partial x} - v_i \frac{\partial^2 F_i}{\partial x^2} = SE_i \quad (45)$$

$$c_{Ei} = \frac{(1 - f_{li}) I_f}{(1 - \lambda_p) L_a} \left( q_{ri} - 2 \frac{q_w}{v_{si}r_{oi}} \frac{\partial q_{ri}}{\partial x} \right) \quad (46)$$

$$v_i = \frac{(1 - f_{li}) I_f q_w q_{ri}}{(1 - \lambda_p) L_a v_{si} r_{oi}} \quad (47)$$

$$SE_i = \frac{I_f f_{li}}{(1 - \lambda_p) L_a} \sum_{j=1}^{n, j \neq i} \frac{\partial}{\partial x} \left( F_j q_{rj} - \frac{q_w}{v_{sj}r_{oj}} \frac{\partial F_j q_{rj}}{\partial x} \right) - \frac{(1 - f_{li}) I_f}{(1 - \lambda_p) L_a} \left( F_i \frac{\partial q_{ri}}{\partial x} - \frac{q_w}{v_{si}r_{oi}} F_i \frac{\partial^2 q_{ri}}{\partial x^2} \right) - \frac{F_i - f_{li}}{L_a} \frac{\partial L_a}{\partial t} \quad (48)$$

575 where  $c_{Ei}$  is the celerity of kinematic wave,  $v_i$  is the diffusivity coefficient, and  $SE_i$  denote source terms.

576 From Eq. (45) we can see that the governing equation for  $F_i$  in the entrainment form is an advection-diffusion equation,  
577 rather than the kinematic wave equation of the flux form. The surface geometric mean grain size  $D_{sg}$  is governed by Eq. (45),  
578 with describes the variation of the surface fractions  $F_i$  from which it is computed. The equilibrium sediment transport rate  $q_{sei}$   
579 is governed by Eq. (45) because we implement a surface-based sediment transport relation as shown in Eq. (34). According to  
580 Eq. (43), the total sediment load per unit width  $q_{st}$  and the geometric mean grain size of sediment load  $D_{lg}$  must also be closely  
581 related to the surface grain size fractions  $F_i$ . Therefore, the diffusion terms in Eq. (45) can lead to dissipation of the kinematic  
582 waves in Figs. 7(b), 7(c), and 7(d).

583 From Eq. (47), we can also see that the diffusivity coefficient  $v_i$  is related to the sediment fall velocity  $v_{si}$ : the larger  
 584 the sediment fall velocity, the smaller the diffusivity coefficient. Thus when we increase the sediment fall velocity arbitrarily  
 585 by a factor of 20 in Section 3.2, the kinematic waves become more evident as a result of the reduction of diffusivity.

586 Moreover if we compare the celerity of kinematic waves in both the flux form and the entrainment form, we have

$$587 \frac{c_{Ei}}{c_{Fi}} = 1 - r_{ci} \quad (49)$$

$$588 r_{ci} = 2 \frac{L_{adi}}{q_{ri}} \frac{\partial q_{ri}}{\partial x} \quad (50)$$

589 where  $L_{adi}$  is the adaptation length for the  $i$ -th size range as defined by Eq. (31). More specifically, the value of  $r_{ci}$  depends on  
 590  $\partial q_{ri} / \partial x$ . For our numerical simulation in Section 3.2,  $\partial q_{ri} / \partial x > 0$  as a result of bed degradation progressing from the upstream  
 591 end, thus leading to a positive value of  $r_{ci}$  and an entrainment celerity  $c_{Ei}$  that is smaller than the corresponding flux celerity  
 592  $c_{Fi}$ . This is consistent with our numerical results: the kinematic waves in Fig. 8 predicted by the entrainment form are somewhat  
 593 smaller than the kinematic waves in Fig. 6 predicted by the flux form.

### 594 4.3 Modeling implications and limitations

595 In Section 3, two numerical cases are conducted to compare the flux form and the entrainment form of the Exner  
 596 equation, but only within 0.2 year after the cutoff of sediment supply. Here we run both numerical cases for a longer time (5  
 597 years). Table 4 shows the results of the case of uniform sediment (as described in Section 3.1) within 5 years, and Table 5  
 598 shows the results of the case of sediment mixtures (as described in Section 3.2) within 5 years. For both cases, the  $\delta$  values,  
 599 corresponding to relative deviation between the flux and entrainment forms, become quite small after 1 year, thus validating  
 600 our assumption that the predictions of the two forms tend to be most evident shortly after disruption, but gradually diminish  
 601 over a longer time scale. Moreover, if the water and sediment supply are kept constant for a sufficiently long time, the flux  
 602 form and entrainment form of Exner equation predict exactly the same equilibrium, in terms of both the channel slope and the  
 603 bed surface texture. Under such conditions, the sediment transport rate (of each size range) equals to the equilibrium sediment  
 604 transport rate (of each size range), and also equals to the sediment supply rate (of each size range).

605 **Table 4.** Quantification of the difference between predictions of the flux form and the entrainment form in the case of uniform  
 606 sediment. The maximum  $\delta$  in the calculational domain are presented for each of 5 years.

		1 yr	2 yr	3 yr	4 yr	5 yr
original $v_s$	$\delta(z_b)$	3.0 %	2.7 %	2.6 %	2.5 %	2.6 %
	$\delta(q_s)$	3.0 %	1.8 %	1.3 %	1.1 %	1.0 %

607

608 **Table 5.** Quantification of the difference between predictions of the flux form and the entrainment form in the case of sediment  
609 mixtures. The maximum  $\delta$  in the calculational domain are presented for each of five years.

		1 yr	2 yr	3 yr	4 yr	5 yr
original $v_s$	$\delta(z_b)$	2.2 %	1.9 %	1.7 %	1.7 %	1.7 %
	$\delta(q_{sT})$	2.9 %	1.8 %	1.5 %	1.4 %	3.9 %
	$\delta(D_{sg})$	5.2 %	3.9 %	3.5 %	4.7 %	3.9 %
	$\delta(D_{lg})$	0.7 %	0.6 %	1.0 %	1.3 %	0.8 %

610

611 Based on the numerical modeling and mathematical analysis in this paper, we suggest that the entrainment form of  
612 the Exner equation be used when studying the river morphodynamics of fine-grained sediment (or more specifically sediment  
613 with small fall velocity). This is because the adaptation length  $L_a$  and the diffusivity coefficient  $v_i$  are large for fine sediment,  
614 but the flux form of the Exner equation does not account for lag effects or diffusivity of individual size fractions, thus leading  
615 to unrealistic simulation results. Such unrealistic simulation results can include an overestimation of advection as sediment  
616 sorts (as shown in the case of sediment mixtures) and an overestimation of the aggradation/degradation rate (as shown in the  
617 case of uniform sediment) when sufficiently small grain sizes (or sediment fall velocities) are considered. Field survey of the  
618 LYR observes no clear sorting waves: the grain size distribution adjusts smoothly both in space and in time, thus indicating  
619 that the more physically-based Entrainment form is more applicable in terms of the sorting processes of the LYR. It should be  
620 noted, however, that the difference in the predictions of the two forms of Exner equation tends to be large shortly after  
621 disruption, but gradually diminishes over time. The flux form of the Exner equation, on the other hand, is particularly applicable  
622 for coarse sediment, or when the sediment transport is dominated by bedload (e.g. gravel-bed rivers). The above results could  
623 have practical implications in regard to a wide range of issues including dam construction, water and sediment regulation,  
624 flood management, and ecological restoration schemes. The results can also be used as a reference for other fine-grained fluvial  
625 systems similar to the LYR, such as the Pilcomayo River in Paraguay/Argentina, South America (Martín-Vide et al., 2014).

626 It should be noted that in the morphodynamic models of this paper, we implement the mass and momentum  
627 conservation equations for clear water (i.e., Eq. (1) and Eq. (2)) to calculate flow hydraulics, instead of the mass and momentum  
628 equations for water-sediment mixture as suggested by Cao et al. (2004) and Cao et al. (2006). More specifically, Cui et al.  
629 (2005) have pointed out that when sediment concentration in the water is sufficiently small, bed elevation can be taken to be  
630 unchanging over characteristic hydraulic time scales, and the effects of flow-bed exchange on flow hydraulics can be neglected.  
631 For the two simulation cases in this paper, the volume sediment concentration  $C$  drops from about  $2 \times 10^{-3}$  to about  $2 \times 10^{-4}$  in  
632 the case of uniform sediment, and from about  $4 \times 10^{-3}$  to about  $4 \times 10^{-4}$  in the case of sediment mixtures, due to the cutoff of  
633 sediment supply at the upstream end. These dilute concentrations validate our implementation of mass and momentum  
634 conservation equations for clear water. Our assumption is not necessarily correct for the entire Yellow River. Upstream of our  
635 study reach, and especially upstream of Sanmenxia Dam, the flow is often hyperconcentrated (Xu, 1999).

636 Considering the fact that in our numerical simulations a constant inflow discharge (along with a flood intermittency  
637 factor) is implemented, and also considering that the morphodynamic time scale is much larger than the hydraulic time scale  
638 in our case, the quasi-steady approximation or even the normal flow approximation can be introduced to further save  
639 computational efforts (Parker, 2004). But one thing that should be noted is that in our simulation results in Section 3, the bed  
640 exhibits an inverse slope near the upstream end. The normal flow assumption becomes invalid under such circumstances, so  
641 requiring a full unsteady shallow water model.

642 By definition, the recovery coefficient  $r_o$  is the ratio of the near-bed to the flux-depth-averaged concentration of  
643 suspended load, and is thus related to the concentration profile. In our simulation  $r_o$  is specified as unity. That is, density  
644 stratification effects of suspended sediment are neglected, and the vertical profile of sediment concentration is regarded as  
645 uniform. However in natural rivers, the value of  $r_o$  can vary significantly under different circumstances (Cao et al., 2004; Duan  
646 and Nanda, 2006; Zhang and Duan, 2011; Zhang et al., 2013). In general, the value of  $r_o$  is no less than unity and can be as  
647 large as 12 (Zhang and Duan, 2011). Therefore according to our mathematical analysis in Section 4.1 and 4.2,  $r_o = 1$   
648 corresponds to a maximum adaptation length  $L_{ad}$ , a maximum diffusivity coefficient  $\nu_i$ , and a minimum ratio of celerities  $c_{Ei}/c_{Fi}$ ,  
649 thus leading to the largest difference between the flux form and the entrainment form. When sediment concentration is  
650 sufficiently high, hindered settling effects reduce the sediment fall velocity. Considering the fact that the sediment  
651 concentrations considered in our simulation are fairly small, hindered settling effects are not likely significant. More study on  
652 stratification and hindered settling effects would be useful in the case of the LYR.

653 In this paper, a one-dimensional morphodynamic model with several simplifications is implemented to compare the  
654 flux-based Exner equation and the entrainment-based Exner equation in context of the LYR. However, a site-specific model  
655 of the morphodynamics of the LYR without these simplifications would be much more complex. For example, in our 1D  
656 simulation we observe bed degradation after the closure of the Xiaolangdi Dam, but we cannot resolve its structure in the  
657 lateral direction. In natural rivers, bed degradation is generally not uniform across the channel width, but may be concentrated  
658 in the thalweg. Moreover, the spatial variation of channel width and initial slope, which are not considered in this paper, are  
659 also important when considering applied problems. The above-mentioned issues, even though not the aim of this paper, merit  
660 future research (e.g. He et al., 2012). Besides, Chavarrias et al. (2018) have reported that morphodynamic models considering  
661 mixed grain sizes may be subject to instabilities that result from complex eigenvalues of the system of equations. No such  
662 instabilities were encountered in the present work.

## 663 **5 Conclusion**

664 In this paper, we compare two formulations for sediment mass conservation in context of the Lower Yellow River,  
665 i.e. the flux form of the Exner equation and the entrainment form of the Exner equation. We represent the flux form in terms  
666 of the local capacity sediment transport rate, and the entrainment form in terms of the local capacity entrainment rate. In the  
667 flux form of the Exner equation, the conservation of bed material is related to the streamwise gradient of sediment transport

668 rate, which is in turn computed based on the quasi-equilibrium assumption according to which the local sediment transport  
669 rate equals the capacity rate. In the entrainment form of the Exner equation, on the other hand, the conservation of bed material  
670 is related to the difference between the entrainment rate of sediment from the bed into the flow and the deposition rate of  
671 sediment from the flow onto the bed. A nonequilibrium sediment transport formulation is applied here, so that the sediment  
672 transport rate can lag in space and time behind changing flow conditions. Despite the fact that the entrainment form is usually  
673 recommended for the morphodynamic modeling of the LYR due to its fine-grained sediment, there has been little discussion  
674 of the differences in predictions between the two forms.

675 Here we implement a 1-D morphodynamic model for this problem. The fully unsteady Saint Venant Equations are  
676 implemented for the hydraulic calculation. Both the flux form and the entrainment form of Exner equation are implemented  
677 for sediment conservation. For each formulation, we include the options of both uniform sediment and sediment mixtures.  
678 Two generalized versions of the Engelund-Hansen relation specifically designed for the LYR are implemented to calculate the  
679 quasi-equilibrium sediment transport rate (i.e., sediment transport capacity). They are the version of Ma et al. (2017) for  
680 uniform sediment, and the version of Naito et al. (accepted subject to revision) for sediment mixtures. The method of Viparelli  
681 et al. (2010) is implemented to store and access bed stratigraphy as the bed aggrades and degrades. We apply the  
682 morphodynamic model to two cases with conditions typical of the LYR.

683 In the first case, a uniform bed material grain size of 65  $\mu\text{m}$  is implemented. We study the effect of cutoff of sediment  
684 supply, as occurred after the operation of Xiaolangdi Dam in 1999. We find that the flux form and the entrainment form give  
685 very similar predictions for this case. Through quantification of the difference between the two forms with a normalized  
686 measure of relative difference, we find that difference in the prediction of bed elevation is quite small ( $< 4\%$ ), but difference  
687 in the prediction of sediment load can be relatively large (about 20%) shortly after the cutoff of sediment supply.

688 The results for the case of uniform sediment can be explained by analyzing the governing equation of sediment load  
689  $q_s$ . In the flux form, the volume sediment transport rate per unit width  $q_s$  equals to the local equilibrium (capacity) value  $q_{se}$ .  
690 In the entrainment form, however, we find that the difference between  $q_s$  and  $q_{se}$  decays exponentially in space. The adaptation  
691 length  $L_{ad} = q_w / (v_s r_0)$  is the key parameter that controls the distance for  $q_s$  to approach its equilibrium value  $q_{se}$ . The larger  
692 the adaptation length, the more different the predictions of the two forms will be. For computational conditions in this case,  
693 the adaption length is relatively small ( $L_{ad} = 1.88 \text{ km}$ ).

694 In the second case the bed material consists of mixtures ranging from 15  $\mu\text{m}$  to 500  $\mu\text{m}$ . We find that the flux form  
695 and the entrainment form give very different patterns of grain sorting. Evident kinematic waves occur at various timescales in  
696 the flux form, but no evident kinematic waves can be observed in the entrainment form. The different sorting patterns are  
697 reflected in the evolution of surface geometric mean grain size  $D_{sg}$ , total sediment load  $q_{sT}$  and geometric mean grain size of  
698 sediment load  $D_{lg}$ , but are not reflected in the evolution of bed elevation  $z_b$ .

699 The different sorting patterns exhibited in the case of sediment mixtures can be explained by analyzing the governing  
700 equation for bed surface fractions  $F_i$ , i.e. the grain size-specific conservation of bed material. We find that in the flux form, the  
701 governing equation for  $F_i$  can be written in the form of a kinematic wave equation. In the entrainment form, however, the

702 governing equation for  $F_i$  is an advection-diffusion equation. It is the diffusion term which leads to the dissipation of kinematic  
703 waves. Moreover, in the advection-diffusion equation arising from the entrainment form, the coefficient of diffusivity is  
704 inversely proportional to the sediment fall velocity. In addition, under the condition of bed degradation the wave celerity is  
705 smaller than that arising from the flux form.

706 Overall, our results indicate that the more complex entrainment form of the Exner equation might be required when  
707 the sorting processes of fine-grained sediment (or sediment with small fall velocity) is studied, especially at relatively short  
708 timescale. Under such circumstances, the flux form of the Exner equation might overestimate advection in sorting processes  
709 as well as the aggradation/degradation rate, due to the fact that it cannot account for the relatively large adaptation length or  
710 diffusivity of fine particles.

## 711 **Notation**

712  $C$  depth-flux-averaged sediment concentration

713  $C_f$  dimensionless bed resistance coefficient

714  $C_c$  dimensionless Chezy resistance coefficient

715  $c_b$  near-bed sediment concentration

716  $c_E$  celerity of the kinematic wave corresponding to  $F_i$  in the entrainment form

717  $c_{F_i}$  celerity of the kinematic wave corresponding to  $F_i$  in the flux form

718  $D$  sediment grain size

719  $E$  dimensionless entrainment rate of sediment

720  $F_i$  volumetric fraction of surface material in the  $i$ -th size range

721  $f_{fi}$  volumetric fraction of sediment in the  $i$ -th size range exchanged across the surface-substrate interface

722  $g$  gravitational acceleration

723  $h$  water depth

724  $I_f$  flood intermittency factor

725  $L_a$  thickness of active layer

726  $L_{ad}$  adaptation length of suspended load

727  $p_{si}$  volumetric fraction of bed material load in the  $i$ -th size range

728  $q_{ri}$  normalized sediment transport rate per unit width for the  $i$ -th size range, defined by Eq. (34)

729  $q_s$  volumetric sediment transport rate per unit width

730  $q_{se}$  equilibrium volumetric sediment transport rate (capacity) per unit width

731  $q_{sf}$  sediment supply rate per unit width

732  $q_w$  flow discharge per unit width

733  $R$  submerged specific gravity of sediment

734  $r_0$  user-specified parameter denoting the ratio between the near-bed sediment concentration and the flux-averaged sediment  
735 concentration  
736  $S$  bed slope  
737  $t$  time  
738  $u$  depth-averaged flow velocity  
739  $u_*$  shear velocity  
740  $v_s$  sediment fall velocity  
741  $x$  streamwise coordinate  
742  $z_b$  bed elevation  
743  $\alpha$  coefficient in Eq. (6) for interfacial exchange fractions  
744  $\Delta t_h$  time step for hydraulic calculation  
745  $\Delta t_m$  time step for morphologic calculation  
746  $\Delta x$  spatial step length.  
747  $\delta$  normalized parameter quantifying the fraction difference between the entrainment form and the flux form.  
748  $\lambda_p$  porosity of bed deposit  
749  $\nu_i$  diffusivity coefficient corresponding to  $F_i$  in the entrainment form;  
750  $\rho$  density of water  
751  $\rho_s$  density of sediment  
752  $\tau_b$  bed shear stress  
753  $\tau^*$  dimensionless shear stress (Shields number)
